Glossary

aesthetasc sensilla Peg-shaped sensillae on the antennules, or first antenna, of crustaceans that detect chemicals dissolved in the surrounding water. Each aesthetasc can contain dendrites from a few, to more than 100 olfactory receptor neurons.

boundary layer The layer of any fluid defined by the velocity gradient that begins at zero flow at the surface of an object and extends upward until the average ambient flow velocity is reached.

concha Several fine, narrow, and curled boney shelves that project into the nasal passages of mammals. Also known as turbinates.

epithelium A thin layer of cells that covers the outer surfaces and lines the inner surfaces of our bodies. A sensory epithelium is such an outer layer that lines a sensory structure and carries the sensory receptor cells embedded in it.

fluid dynamics The field of engineering involved in the description, characterization, and manipulation of the behavior of fluids, particularly water and air.

neuromast a sensory structure in the skin of fish that detects changes in the direction, or intensity of water movement.

The distribution of chemicals resulting from the interaction of flowing fluid with a source of volatile chemicals is commonly called a plume, which has a discontinuous patchy structure (Figure 1). The internal structure of odor plumes changes predictably with both distance downstream from the source and distance from centerline across the plume, and behavioral experiments indicate that odor-tracking animals alter their tracking behavior in response to these changes. In most organisms tested, odor-tracking behavior requires the intermittent olfactory stimulation generated by the patchy structure of the plume to generate upstream movement and successful location of the source. Neurons at all levels of the olfactory system are sensitive to intermittent stimulation, and some circuits appear to preserve the temporal activation patterns experienced

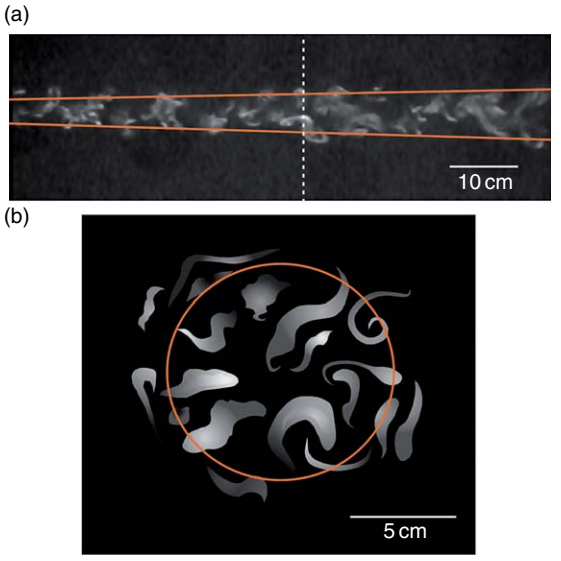

Figure 1 Two perspectives on instantaneous views of smoke visualizations of wind-borne odor plumes. (a) A single field from a video recording of a $TiCl_4$ smoke plume in a laboratory wind tunnel viewed from above. The time-averaged plume boundaries are represented by red lines running from the upwind to downwind side of the image (i.e., left to right). In this image, the wind is blowing from left to right at 75 cm s^{-1}, and the source is a 0.7 cm filter paper disk to which a drop of $TiCl_4$ has been applied. Since this is the same source used in insect odor-tracking experiments, according to the laws of fluid dynamics, the structure of the plume should be similar to the odor plume experienced by the insects. (b) A schematic approximation illustrating the tracker's eye view of the smoke plume visualization depicted in (a) above. The red circle represents an extension of the time-averaged plume boundaries in (a) onto this cross section. White dashed line is approximately 1 m downwind from the source. (a) Reproduced from Webb, B., Harrison, R. R., and Willis, M. A. 2004. Sensorimotor control of navigation in arthropod and artificial systems. Arthropod Struct. Dev. 33, 301–330, with permission from Elsevier.

in a plume and relay them to higher processing centers in the brain. Recent studies using simulation models and odor-guided robots are leading to tests of biological hypotheses that would be difficult or impossible to address with living organisms, and are also leading to the first man-made plume-tracking systems.

4.42.1 Ubiquity of the Use of Olfaction to Locate Distant Resources

Virtually every object on our planet, biotic or abiotic, sheds molecules into the environment. If these molecules are in high enough concentrations, they can be detected and processed by the olfactory systems of animals as they move through the environment, seeking opportunities to forage (Arbas, E. A. *et al.*, 1993; Weissburg, M. J. and Zimmer-Faust, R. K., 1994; Basil, J. A. *et al.*, 2000; Raguso, R. and Willis, M., 2002; Ferner and Weissburg, M. J., 2005; Raguso, R. and Willis, M., 2005), mate (Cardé, R. T. and Minks, A. K., 1997 and citations therein), locate home and appropriate territories (Wolf, H. and Wehner, R., 2000), and avoid predators (Susswein, A. J. *et al.*, 1982). The behavior of two fluids, air and water, dominates the distribution of these molecules, and to a large degree determines how living organisms are able to use this molecular information to adapt their behavior, increasing their probability of survival and reproduction (Vickers, N. J., 2000; Weissburg, M. J., 2000).

Flow-borne odor plumes provide information important for aquatic, marine, and terrestrial organisms that walk, fly, and swim to locate resources. Despite these seemingly different environments and modes of locomotion, the paths generated by these animals often appear remarkably similar (Figures 2 and 3). Whether this similarity in tracking trajectories stems from a similarity in underlying physiological and behavioral mechanisms is almost entirely unknown.

4.42.2 Distribution of Odorants in the Environment

Our understanding of how volatile chemicals are distributed in the environment and the effects that this has on the behavior of animals tracking odor plumes has advanced considerably in recent years. This has resulted from behavioral biologists working together with fluid dynamics engineers to study the fine structure of odor plumes in different and dynamically changing environments (Wright, R. H., 1958, Figure 1; Murlis, J. and Jones, C. D., 1981; Murlis, J. *et al.*, 1990; Weissburg, M. J. and Zimmer-Faust, R. K., 1993; Griffiths, N. and Brady, J., 1995; Murlis, J. *et al.*, 2000; Webster, D. R. and Weissburg, M. J., 2001). Odor plume structure has significant effects on the tracking behavior of almost every animal in which this has been tested (Vickers, N. J., 2000; Weissburg, M. J., 2000).

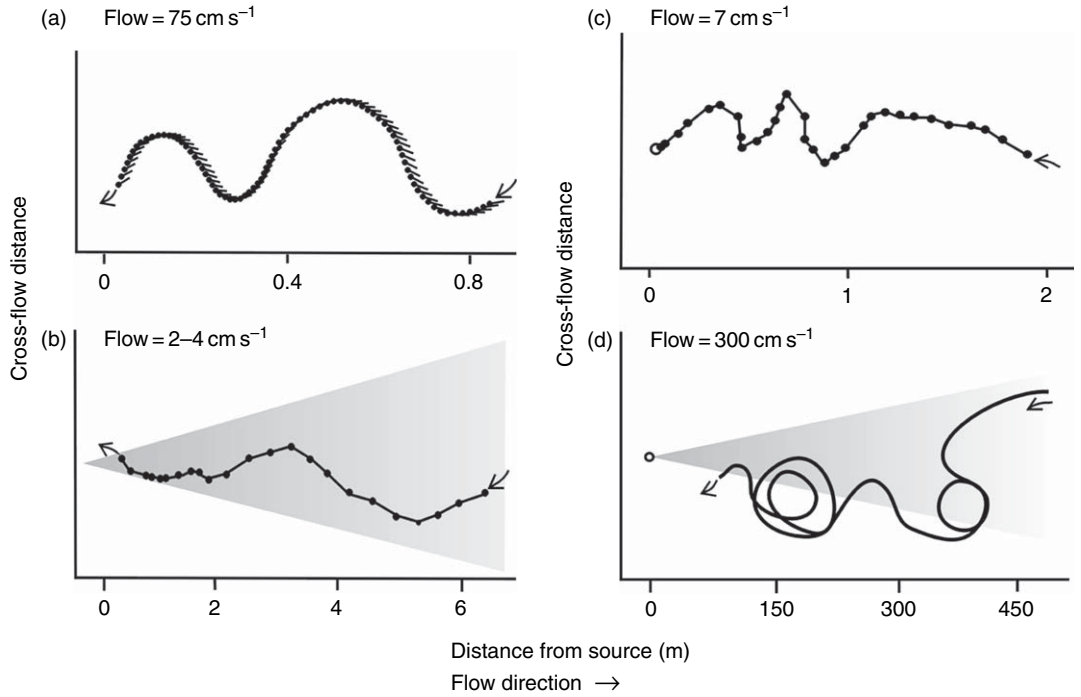

Figure 2 Movement paths of animals tracking plumes while supported by the fluid through which they are tracking, as viewed from above. (a) Flight path of a male moth, *Manduca sexta*, tracking an airborne plume of female sex-attractant pheromone in a laboratory wind tunnel. (b) Swimming path of the Antarctic fish, *Trematomus bernachii*, while tracking a water-borne plume of prey extract recorded in its natural environment. (c) Swimming path of the cephalopod mollusk, *Nautilus pompilus*, tracking a water-borne plume of prey extract recorded in a laboratory flume. (d) Observer's approximation of the flight path of a Turkey vulture, *Cathartes aura*, tracking an airborne plume of ethyl mercaptan, a volatile chemical associated with dead animals. 4.42.2.1 Diffusion versus Turbulent Diffusion

The distribution of volatile odorants in fluids is determined primarily by the processes of diffusion and turbulence (Murlis, J. *et al.*, 1990; Vogel, S., 1994; Weissburg, M. J., 2000). For animals larger than approximately 1 mm, turbulence is usually the more important of these two processes (Weissburg, M. J., 2000). According to the laws of fluid dynamics, the behavior of air and water are governed by similar constraints, and their behavior can be predicted depending on viscosity, flow velocity, and density (Vogel, S., 1994). Turbulence can be described as velocity variations in the flow itself or can result from velocity differences caused when flowing fluid interacts with fixed objects in the flow. From a fluid dynamical perspective, plumes are typically described by a statistical distribution that has been depicted as a smooth concentration gradient that diminishes both with distance downstream from the source and across the flow from the plume's centerline to the edges, both laterally and vertically (Bossert, W. H. and Wilson, E. O., 1963). However, a snapshot of an odor plume reveals a discontinuous structure composed of patches of odor separated by clean air (Figure 1).

The olfactory sensory cells and central processing circuitry of animals do not typically respond to distributions of odorants averaged over time. Rather, they respond to changes in sensory stimuli and initiate behavioral responses in tens or hundreds of

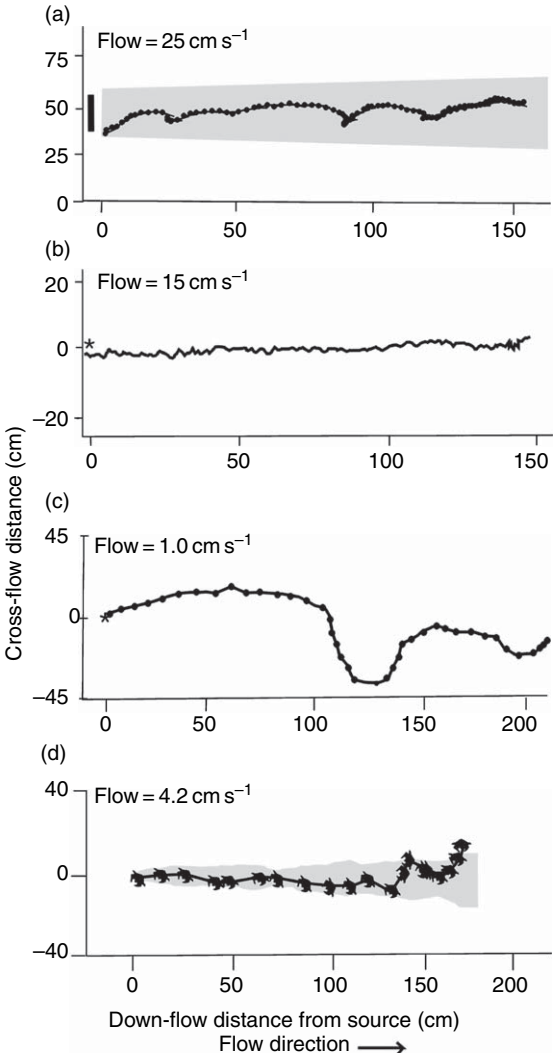

Figure 3 Movement paths of substrate-borne animals tracking air- and water-borne odor plumes as viewed from above. D., and Wethey, D. S. 1995. Odor plumes and animal navigation in turbulent water flow: A field study. Biol. Bull. 188, 111–116, with permission from Marine Biological Laboratory and the author.

milliseconds. High-frequency sampling of plumes performed in water (Moore, P. A. and Atema, J., 1991) and air (Vickers, N. J. *et al.*, 2001) reveals the structure underlying time-averaged plume statistics. Any tracker moving across the plume will have an increased probability of encountering filaments of higher concentration as it moves toward the plume centerline, across the flow, from any direction

(Figure 1(b)). Likewise, in both air (Murlis, J. and Jones, C. D., 1981; Murlis, J. *et al.*, 1990; 2000) and water (Webster, D. R. and Weissburg, M. J., 2001), a tracker will have an increased probability of encountering higher concentration plume filaments as it moves into the flow toward the source. The lateral and longitudinal decrease in concentration (i.e., molecules/volume of fluid) results primarily from turbulent mixing of the filaments within the plume, not diffusion. Behavioral experiments suggest that plume-tracking animals use these changes in plume structure to adapt their behavior. Considering the speed of most animal locomotion and fluid flow in most of earth's environments (i.e., tens of centimeters to meters/second) together with the small distances/time generated by diffusion (*c.* 9.5 cm in 1 h for a typical insect sex pheromone in air; Loudon, C., 2003), it is easy to understand that turbulence dominates the distribution of the stimulus and thus the structure of the tracking behavior observed from odor-tracking animals.

4.42.2.2 Environmental Effects on Odorant Distribution

Although we can measure the differences in plumes in different environments (Weissburg, M. J. and Zimmer-Faust, R. K., 1994; Griffiths, N. and Brady, J., 1995; Murlis, J. *et al.*, 2000), the primary significance of these differences stems from the fact that plume-tracking animals show dramatically different behavior and success at source location in different turbulent flows. Even though many organisms are superbly adapted to track plumes to their sources, ambient flow and turbulence conditions can exist in natural environments that make the task almost impossible to perform (Elkinton, J. S. *et al.*, 1987; Weissburg, M. J. and Zimmer-Faust, R. K., 1993; Griffiths, N. and Brady, J., 1995).

4.42.3 Plume Characteristics Important to Plume-Tracking Organisms

Behaviors that are initiated or modulated by olfactory information can be difficult to study because the primary stimulus is out of the control of the researchers almost as soon as it evaporates from the dispenser. However, even with this major difficulty, it is possible to define three broad categories of information known to be detected by plume-tracking organisms: (1) temporal/spatial structure of molecules distributed in the plume, (2) quality of the molecules in the plume, and (3) quantity of molecules in the plume. Experimental manipulation of variables in each of these three categories results in significant changes in the structure of the paths taken by odor-tracking organisms as they orient and move upstream or upwind toward the source (Belanger, J. H. and Willis, M. A., 1996).

4.42.3.1 Temporal/Spatial Structure

The patchy structure of odor plumes has been known to researchers studying olfactory orientation for some time (Wright, R. H., 1958), but its dramatic effect on orientation and tracking behavior has been fully appreciated only recently (Cardé, R. T. and Minks, A. K., 1997). The intermittent stimulation resulting from an odor plume is necessary for most animals tested to orient to odor, except for the fruit fly *Drosophila melanogaster* (Budick, S. A. and Dickinson, M. H., 2006), one species of moth (*Cadra cautella*; Justus, K. A. and Cardé, R. T., 2002), and small organisms in a detectable gradient (e.g., microorganisms, copepods; Weissburg, M. J., 2000). Recent results show that the temporal/spatial structure of an odor plume has a more dramatic effect on the structure of tracking behavior than any other known variable (Mafra-Neto, A. and Cardé, R. T., 1994; Vickers, N. J. and Baker, T. C., 1994). For example, it has been observed that sources emitting similar levels of chemicals but manipulated to generate structurally different plumes elicit characteristically different behavior from males approaching from downwind (Charlton, R. E. *et al.*, 1993; Mafra-Neto, A. and Cardé, R. T., 1994; Vickers N. J. and Baker T. C., 1994; Willis, M. A. *et al.*, 1994). A seminal study by Vickers N. J. and Baker T. C. (1992) showed that moths alter their tracking performance in response to both the timing of encounters with structural elements of the plume and the concentration detected from those elements. Their study used a puffing device to experimentally control the interval between puffs while they varied the concentration of the source independently. By altering these variables independently, Vickers N. J. and Baker T. C. (1992) demonstrated that decreasing the number of pheromone puffs encountered enabled their moths to track upwind to high concentrations that they normally could not.

Dogs challenged to track trails of odor deposited on the ground were more successful (over 90%) tracking a path of discontinuous patches (i.e., human foot steps) than a continuous trail of odor (Hepper, P. G. and Wells, D. L., 2005). So the combination of discrete

patches of odor with no odor in between, and the active sniffing behavior performed while tracking, results in an intermittent odor signal that appears to be required for dogs to track substrate-borne trails. In addition, recent measurements of respiratory air flow in dogs during the tracking of wind-borne odors, combined with modeling of the flow through the upper respiratory tract, suggest that a nearly continuous inflow of odor-bearing air over the olfactory epithelium is probable, even while running (Steen, J. B. *et al.*, 1996). Thus, in this situation, some if not all of the temporal/spatial structure of the odor might be preserved to be presented to the olfactory epithelium.

What effect does the sniffing behavior of vertebrate animals have on the structure of the plume? One possibility is that the increased flow velocity interacting with the concha in the nasal passages would result in increased turbulence and a completely mixed sample arriving at the olfactory epithelium. This could effectively smooth out the dramatic peaks and valleys in the odor signal caused by the filamentous structure of the plume. Whether this actually happens, and how it might affect the trackers' behavior, awaits further study.

Crustaceans also sniff as a way to enhance or alter their olfactory inputs (Schmidt, B. C. and Ache, B. W., 1979). When responding to odor, they move the olfactory part of their second antennae (i.e., antennules) through the water very rapidly (Schmidt, B. C. and Ache, B. W., 1979). Flicking behavior, as this is known, has been shown to decrease the boundary layer around the antennules and force the odor filaments into the array of odor-detecting sensilla (Koehl, M. A. R., 2006). The effect of the shallower boundary layer is to decrease the distance that the odor molecules must diffuse to reach the receptors and thus enhances the extraction of odor information from the environment. To date, the effects of flicking behavior on the perceived structure of an odor plume have not been measured directly, and how this could affect the animal's tracking behavior has not been determined.

4.42.3.2 Quality

In moths, the best-known example, detection of the number and type of molecules in an odorant plume is determined by the combination of peripheral sensory structures and central processing. This has been demonstrated in behavioral experiments by independently manipulating the structure of the plume and the chemical compounds making up that structure (Vickers, N. J. and Baker, T. C., 1992). Two sensory cells that detect the two components of the pheromone required for behavioral activity are housed a few microns apart in the same sensory hair on the antenna. Their spatial coincidence means that they are perfectly situated to detect temporal coincidences of odorant components in the pheromone. This arrangement of sensory structures, in combination with central coincidence detecting interneurons (Christensen, T. C. and Hildebrand, J. G., 1988), is capable of resolving spatial/temporal separation of structural elements in the plume in the millisecond (i.e., millimeter) range. At the wind speeds at which these experiments were performed, this resulted in male moths being able to discriminate between odorant encounters approximately 3 m apart (Baker, T. C. *et al.*, 1998). Thus, in a fundamental way, the ability of these animals to use blends of odorant compounds in a meaningful way may *require* the patchiness of the distribution and detection that characterizes plumes. The components of a behaviorally relevant blend of compounds must be detected nearly simultaneously to activate a behavioral response (Vickers, N. J. and Baker, T. C., 1992; Baker, T. C. *et al.*, 1998; Vickers, N. J., 2006).

4.42.3.3 Quantity

Concentration of chemicals in the plume or plume filaments is known to change predictably with distance from the source. As the individual filaments expand as a result of turbulence and, as the period from evaporation from the source to detection gets longer, the same amount of chemicals is spread over a larger space, that is, dilution, resulting in lower concentration. This will also result in the ratio of the peak concentration to the mean decreasing with distance from the source. Thus, the peak concentration will be lower, and the time from odor onset to peak concentration detected upon contacting a filament of odor will be longer as the plume moves farther and farther downwind. It is clear that animals modulate their behavior according to their distance from the source and, when tested independently, they modulate their behavior according to changes in concentration. Thus, plume-tracking animals appear to modulate their behavior according to both changes in odorant concentration and the spatial/temporal structure of those concentration differences, and these responses can operate independently (Vickers, N. J. and Baker, T. C., 1992).

4.42.4 Tracking Odor Plumes Typically Requires Information from Multiple Senses

In most known cases, plume-tracking animals require information from multiple sensory systems to successfully perform this task. The environmental cue that the tracking organism uses to orient its steering is the direction of the fluid flow, not a nonexistent odor gradient. The preferred direction of orientation with respect to the flow, if there is one, is usually modulated by the presence or absence of the odor.

4.42.4.1 Orientation to Flow

The direction of flow may be extracted from the environment directly by the deflection of a mechanosensory structure, for example, antennae and wind-sensitive hairs in arthropods (Arbas, E. A., 1986), superficial neuromast sensors in the lateral line system in fish (Baker, C. F. and Montgomery, J. C., 1999), feathers or wind-sensitive breast feathers in birds (Gewecke, M. and Woike, M., 1978), or facial whiskers in mammals (Dehnhardt, G. *et al.*, 1998). When the animal is in contact with a solid substrate, these sensors will provide the speed and direction of the flow. However, if the animal is suspended in the flow, like a swimming fish or flying bird or insect, the information provided by these sensors will be the speed of the organism with respect to the flow. Flying or swimming animals almost always detect the flow direction indirectly by determining how they are moving with respect to the nonmoving parts of their environment (e.g., the ground or trees). The single well-documented contradiction to this statement is the Mexican blind cave fish (Baker, C. F. and Montgomery, J. C., 1999). However, these results suggest that the lateral line system could provide flow direction to any fish.

All well-described examples of indirect detection of flow direction involve animals using visually detected movement with respect to an assumed stationary environment. In the case of flying moths, it is thought that they are able to compute the wind speed and direction by comparing their intended course to their realized course, with any difference between the two assumed to be caused by wind-induced drift (Marsh, D. *et al.*, 1978). This method of using visual information to steer with respect to the wind direction and speed while tracking an odor plume was first demonstrated by Kennedy J. S. (1940) in female mosquitoes tracking human breath. Kennedy and his co-workers went on to demonstrate that using visually perceived wind information to steer and control flight speed (known as optomotor anemotaxis) was ubiquitous in flying insects, whether or not they were tracking odor (Kennedy, J. S. and Marsh, D., 1974; Marsh, D. *et al.*, 1978; David, C. T., 1986). The use of visually detected flow information to control the speed and direction of movement has also been demonstrated clearly in male rainbow trout tracking female oviduct extract upstream (Emanuel, M. E. and Dodson, J. J., 1979).

4.42.4.2 Orientation to Odors

Animals that use odor cues to track plumes may use two hypothetical mechanisms to acquire chemical information on which to base their steering decisions: (1) spatial comparisons of odor inputs to bilaterally symmetrical sensors (i.e., antennae or nostrils), and (2) temporal comparisons of odor inputs sensed at different points in time (Frankel, G. S. and Gunn, D. L., 1961; Schöne, H., 1984; Dusenberry, D. B., 1992). It is possible that either of these two strategies may be more effective at tracking plumes generated under different environmental and flow conditions (Weissburg, M. J., 2000). These two hypotheses are typically referred to as spatial and temporal strategies respectively. Since the vast majority of odor-tracking animals have bilaterally symmetrical odor sensors, the possibility that both strategies could be operating at the same time, either synergistically or independently, has always been acknowledged (Frankel, G. S. and Gunn, D. L., 1961; Schöne, H., 1984). However, careful experiments necessary to resolve these questions have rarely been pursued (Martin, H., 1965; Hangartner, W., 1967; Bell, W. J. and Tobin, T. R., 1981; Borst, A. and Heisenberg, M., 1982; Johnsen, P. B. and Teeter, J. H., 1985).

4.42.4.2.1 Spatial comparisons of odor concentration (bilaterally symmetrical sensors)

Animals walking slowly through slower flows experience relatively less turbulent plumes because the surfaces they walk on damp its vertical component (Weissburg, M. J., 2000). Slow movement relative to the slowly moving plume may allow such plume trackers to steer to remain in the plume by using a spatial sampling strategy to experience the odor edges defined by the rapid drop of concentration at the lateral margins of the plume (Figure 1(b)). Chemical concentration differences that would inform these steering decisions could be sensed

instantaneously using bilateral sensors, or because of the relatively low encounter rate with odor structures in the plume, the same sensors could enable time averaging of concentration in the central nervous system. If an odor-tracking organism were using spatial comparisons to control its maneuvering, it would be possible, knowing the plume structure, to predict when and in what direction it would turn. Recent observations in plume-tracking cockroaches suggest that many, but perhaps not all, of the turns in their walking tracks may result from bilateral comparisons (Figure 4). Recent analyses indicate that knowledge

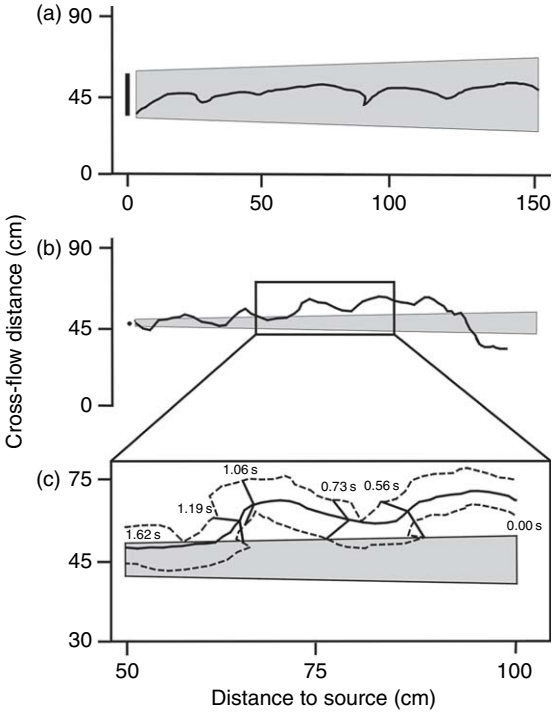

Figure 4 Movement paths of male cockroaches as they track female sex-attractant pheromone plumes of different structures. (a) Walking path of a male cockroach tracking a turbulent plume issuing from a 14.3 cm wide source in a laboratory wind tunnel. Note that the cockroach never approaches the lateral pheromone-clean air boundary of the plume. (b) Walking path of a male cockroach tracking a turbulent plume issuing from a source 0.7 cm wide (i.e., point-source plume). Note the regular sinusoidal zigzagging turning executed by this male as he tracked the plume upwind toward the source. (c) Detail of (b) above showing the position and orientation of the animal's antennae during a brief sequence of turning. In all images, the fluid flows from left to right, and the flow velocities for each example are presented in each panel. Reproduced from Willis, M. A. and Avondet, J. L. 2005. Odor-modulated orientation in walking male cockroaches, *Periplaneta americana* (L.), and the effects of odor plumes of different structure. J. Exp. Biol. 208, 721–735, with permission of the Company of Biologists Ltd.

of the plume structure should allow prediction of sensor spacing appropriate to support bilateral concentration comparisons (Webster, D. R. *et al.*, 2001).

4.42.4.2.2 Temporal comparisons of odor concentration (sensors small relative to the scale of the plume, memory required)

In contrast, animals swimming or flying are moving relatively more rapidly, through faster turbulent flows and thus experience an odor plume at a much faster rate (which makes it essentially a continuous series of pheromone-clean air edges). These animals may not have time to extract information about changes in the plume fast enough to support adaptive maneuvering using a spatial strategy. To a system focused on the timing of the odor inputs and not where it is, the edge of the plume is just another odor on–off in the sequence (Webster, D. R. *et al.*, 2001).

The inability, in most cases, to determine when and where an organism detects an odor plume, both in relation to the plume and in relation to the animals' own preceding and subsequent behavior, has made it almost impossible to determine which of the existing hypothetical mechanisms may underlie the behavior we observe. In only one case has the physiological response of the olfactory sensors to plume structure been measured during a plume-tracking performance (Vickers, N. J. and Baker, T. C., 1994). Even in this example, the olfactory responses were measured from a surgically detached antenna carried by the odor-tracking individual, not from the antennae of the individual actually performing the tracking behavior.

4.42.4.3 Importance of Active Sampling Behaviors to Odor Detection and Processing

Loudon C. and Koehl M. A. R. (2000) have shown that flows induced by pheromone-activated wing fanning behavior in *Bombyx mori* males may enhance the ability of the males to respond to pheromone during plume-tracking behavior. Measurements of air flow over the male moth's feathery antenna showed rhythmically varying velocities that matched the moths' wing beat frequency. Such a rhythmically varying flow would cause intermittent encounters between the antennae and any odor plume near enough to be drawn into the flow generated by the beating wings. When the wings of *B. mori* males were removed, their success at locating the females decreased (Ishida, H. *et al.*, 1996). Similar active sampling behaviors are generated by lobsters, crayfish,

and other crustaceans when they are tracking odors as they rapidly flex their antennules driving their chemosensors through the plume in a behavior known as flicking (Schmidt, B. C. and Ache, B. W., 1979; Koehl, M. A. R., 2006).

4.42.5 Man-Made Odor Tracking Systems

Although our knowledge and understanding of odor plumes and the neural and behavioral responses of plume-tracking organisms is far from complete, enough is known that some have begun to apply this knowledge to man-made odor-tracking systems. Some of the first robotic odor-tracking systems were conceived and fabricated by Russell R. A. (1999) to provide the chemical communication capabilities of social insects (e.g., ants and bees) to interacting robots. The idea was to use odor tracking in a manner similar to ants and termites, as a way to mark trails through the environment, to guide the foraging behavior of other members of a robot team. Russell's first attempts included fabricating the entire system, from the robot to the odor detectors (Russell, R. A., 1999). These early robots were able to track a volatile chemical trail deposited on the substrate for some time and distance. However, in both the robotic system and its insect model, the source of the odor (i.e., the odor trail) was always very close to the tracker. These initial experiments then led to the development of wind direction sensors and tracking algorithms that mimicked the pheromone-tracking behavior of male silk worm moths, *B. mori* (Russell, R. A. *et al.*, 1995). These new sensory and control systems performed well enough to guide a mobile robot around obstacles in a laboratory environment and successfully locate a source of volatile chemicals (Russell, R. A. *et al.*, 1995). Similar experiments were being conducted in other laboratories with similar results (Ishida, H. *et al.*, 1994).

To date, the most significant hindrances to the development of odor-tracking robots are the chemical detectors; the robots' olfactory sensors. None of the currently available off-the-shelf man-made odor detectors approach the temporal response or exquisite sensitivity of their biological precursors. In one series of experiments, this problem was overcome by surgically removing the biological odor detectors (i.e., the antennae of male moths) and mounting them on a mobile robot (Kuwana, Y. *et al.*, 1995). Although these experiments demonstrated the efficacy of interfacing living (i.e., dying) tissue with simple electronics, and generated predictable odor-activated steering responses, the relatively short life of the antenna after removal from the insect makes this alternative impractical.

Another approach has been to fabricate robotic odor-tracking systems explicitly as a means to test biological hypotheses about how animals track odor plumes (Grasso, F. W. *et al.*, 2000; Edwards, S. *et al.*, 2005). These robotic studies usually form part of a multipronged research program aimed at working iteratively between robotic or simulation experiments and animal studies. In these studies, simulation and mobile robot experiments are developed using new and existing biological knowledge, and their results then are used to inform the design and interpretation of the subsequent behavioral or neurophysiological studies. Results from some of these robotic experiments (Grasso, F. W. *et al.*, 2000; Edwards, S. *et al.*, 2005) have caused the reexamination of our previous understanding of odor tracking.

4.42.6 Conclusions

If we could know when the organisms detected an odor filament together with the preceding and subsequent behavior, we could begin to understand how the animals are using the information to control their behavior. Do they modify their tracking behavior based on each encounter with odor as suggested by recent experiments (Mafra-Neto, A. and Cardé, R. T., 1994; Vickers, N. J. and Baker, T. C., 1994), or do they continuously modulate an odor-activated internal program as proposed earlier (Kennedy, J. S., 1983). Or does the trackers' response change in a context-dependent manner? Do some animals have alternative tracking algorithms that are employed in different environmental conditions (i.e., different plumes structures) or does a single simple tracking algorithm yield apparently different but adaptive behavior as the animal actively interacts with different plume structures generated in different environmental conditions? Much is known about this interesting biological phenomenon, but many lacunae in our knowledge at all levels of organization, environmental, neural, and behavioral, remain to be filled before a complete understanding is revealed.

4.43.1 Introduction

The majority of vertebrates have dual independent olfactory systems; possessing an accessory olfactory system (AOS) in addition to the main olfactory system. The AOS has attracted a great deal of attention in recent years because of a growing recognition of the essential role in chemical communication and the regulation of social behaviors this system plays. Key elements of the AOS (Figure 1) include

1. the vomeronasal organ (VNO), a chemoreceptive structure situated at the base of the nasal septum which houses the vomeronasal sensory neurons (VSNs);
2. the accessory olfactory bulb (AOB), a structure of the forebrain that receives input from the VNO serving as the first processing center of vomeronasal information; and
3. higher olfactory centers that receive direct or indirect information from the AOB.

These higher brain structures include, in mammals, the medial amygdala and parts of the cortical and posterior amygdala, the bed nucleus of the accessory olfactory tract (BAOT), the bed nucleus of the stria terminalis (BST), and the medial hypothalamus. The focus of this chapter will be on physiology and function of the VNO and AOB. Whenever possible, we attempt to link genetic information with anatomical, physiological, and behavioral approaches. Because the mouse has become the principal model system for a genetically driven, systems-oriented approach, the focus of this chapter will be on rodent AOS function. However, it is important to realize that the precise role of the AOS must be viewed in close relationship to species-specific adaptations. Indeed, the initial discovery of pheromonal–behavioral signaling through specific neural pathways was pioneered in invertebrate biology, and many of the fundamental concepts of VNO–AOB function have developed from research in nonmammalian species.

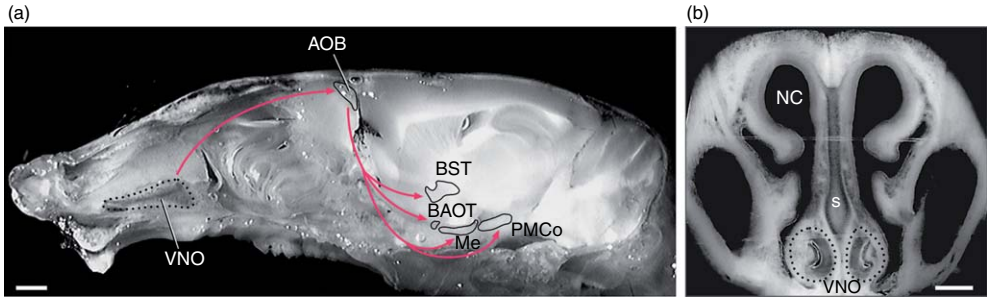

Figure 1 Anatomy of the accessory olfactory system. (a) Perisaggital view of the mouse head with a superimposed diagram representing the accessory olfactory pathway. Sensory inputs in the accessory olfactory system are detected by sensory neurons in the vomenonasal organ (VNO), a bilateral tubular structure in the anterior region of the nasal cavity (see (b)). An extensive network of blood sinuses is located at the lateral external wall of the organ. Together with a band of cavernous erectile tissue, it provides the hardware for a vomeronasal pump that aids in stimulus delivery. Axons of the vomeronasal sensory neurons (VSNs) project to the accessory olfactory bulb (AOB), which in turn transmits sensory information to the bed nucleus of the stria terminalis (BST), the bed nucleus of the accessory olfactory tract (BAOT), and the amygdala, that is, the medial amygdaloid nucleus (Me) as well as the posteromedial cortical amydaloid nucleus (PMCo). The information is then transmitted from the amygdala to specific nuclei of the hypothalamus. These tertiary projections to the hypothalamic region are also known as the neuroendocrine hypothalamus. This area controls the release of hormones by the pituitary and therefore modulates the endocrine status of the animal. As a reference for the location of the VNO, the septum was partially removed to reveal the turbinates of the main olfactory organ. Scale bar = 1.5 mm. (b) Transmitted light image of a coronal section through a postnatal day 7 mouse head showing the location of the bilateral VNO (dashed circles) at the base of the nasal septum (S). NC, nasal cavity. Scale bar = 200 μm.

4.43.2 A Brief Historical Perspective

The VNO was discovered by Ludvig Jacobson (and hence often referred to as Jacobson's organ) and was originally described in a Danish publication (Jacobson, L., 1813). This work has recently been translated into English and is thus accessible to a wider audience (Doving, K. B. and Trotier, D., 1998; Jacobson, L. *et al.*, 1998). Jacobson described the organ in a variety of domesticated mammals, some wild carnivores, ungulates, and marine mammals. He assumed that the organ was secretory in nature but suspected that it could also function as a sensory organ.

Balogh C. (1860), Klein E. (1881), Piana G. P. (1882), and Retzius G. (1894) observed similarities in the morphology of sensory neurons in the main olfactory epithelium and VNO, and proposed a common function between the cells. During the following years, the presence of the VNO was confirmed in most mammals (von Mihalkovics, V., 1899; Perlman, S. M., 1934). A review by Doving K. B. and Trotier D. (1998) has reproduced the excellent quality of cross sections of the mouse VNO originally published by von Mihalkovics V. (1899).

The existence of the AOB in mammals was recognized by von Gudden B. (1870). McCotter R. E. (1912) was the first to clearly demonstrate that the AOB is a brain structure dedicated to the reception of vomeronasal nerve (VN) fibers, and that it gives off fibers that join the lateral olfactory tract. He suggested that the olfactory system should be divided into two distinct subsystems, namely an ordinary and an AOS.

Beginning in the 1930s and extending to the 1950s, Lord Adrian began to use electrophysiological methods to record extracellular activity from the VNs of the rabbit. He was unable to show a reaction to chemical stimuli in the VNO, but he noted considerable rhythmic activity in response to localized pressure (Adrian, E. D., 1955).

During the 1950s and 1960s, an intense period of pheromone research began. Following the seminal work on insect pheromones (Karlson, P. and Lüscher, M., 1959), behavioral endocrinologists had discovered several pheromonal effects in mice and a consensus emerged that these effects require a functional olfactory system. Winans S. S. and Scalia F. (1970) suggested that some of these effects might depend on a functional AOS. This idea eventually led to the dual olfactory hypothesis (reviewed by Halpern, M., 1987), which proposed that distinct parallel pathways could be traced from the periphery of the main and AOSs into the telencephalon and diencephalon of all animals possessing these two chemoreceptive systems. As pointed out by Halpern M. (1987), a main corollary of this hypothesis is that each system should be involved in distinct behavioral

domains. During the 1970s and 1980s, research concentrated on testing this hypothesis and its corollary by using a combination of anatomical, behavioral, and physiological approaches. This work has been summarized in a number of excellent reviews (Burghardt, G. M., 1970; Madison, D. W., 1977; Keverne, B., 1979; Wysocki, C. J., 1979; Johnston, R. E., 1983; Keverne, E. B., 1983; Meredith, M., 1983; Halpern, M., 1987; Wysocki, C. J. and Meredith, M., 1987).

The 1990s saw an explosion of interest in AOS function triggered by the application of molecular biological and genetic approaches, together with the use of more sophisticated electrophysiological recording techniques. A significant finding was the segregation of the mouse and rat vomeronasal system into two major subsystems, each expressing distinct classes of signal transduction-related molecules (Halpern, M. *et al.*, 1995; Berghard, A. *et al.*, 1996; Jia, C. and Halpern, M., 1996). This was followed by the identification of the first (Dulac, C. and Axel, R., 1995) and second families of vomeronasal receptor genes (Herrada, G. and Dulac, C., 1997; Ryba, N. J. and Tirindelli, R., 1997; Matsunami, H. and Buck, L. B., 1997), and the cloning of the ion channel TRPC2 (canonical transient receptor potential channel type 2) (Liman, E. R. *et al.*, 1999). The first patch clamp recordings from single VSNs were carried out by Trotier D. *et al* (1993), Taniguchi, M. *et al.* (1995), and Liman E. R. and Corey D. P. (1996). In parallel, gene-targeting methods were developed by Mombaerts P. *et al.* (1996), which subsequently led to an analysis of the axonal projection patterns of specific subsets of VSNs (Belluscio, L. *et al.*, 1999; Rodriguez, I. *et al.*, 1999).

Since 2000, research activities aimed at understanding AOS function have further increased. The year 2000 saw the development of reduced mouse VNO preparations that allowed for simultaneous recording of stimulus-induced activity from hundreds of VSNs (Holy, T. E. *et al.*, 2000; Leinders-Zufall, T. *et al.*, 2000) leading to the identification of the first prospective pheromones acting on mammalian VSNs (Leinders-Zufall, T. *et al.*, 2000). Next came the targeted deletion of specific signal transduction genes, which enabled, for the first time in the AOS, a correlation between gene function, cellular activity, and behavioral changes (Del Punta, K. *et al.*, 2002a; Leypold, B. G. *et al.*, 2002; Stowers, L. *et al.*, 2002). Progress in understanding VSN signal transduction mechanisms (Lucas, P. *et al.*, 2003) was quickly followed by the finding that a subset of VSNs function as detectors of peptide ligands of the major histocompatibility complex (MHC), and that these peptides influence selective pregnancy termination (the Bruce effect) (Leinders-Zufall, T. *et al.*, 2004). In parallel, the first recordings from AOB neurons in freely behaving mice were undertaken, making it now possible to correlate neuronal activity in the AOB with specific behavioral changes (Luo, M. *et al.*, 2003). Several reviews have summarized these most recent aspects of AOS research (Dulac, C. and Torello, A. T., 2003; Brennan, P. A. and Keverne, E. B., 2004; Luo, M. and Katz, L. C., 2004; Mombaerts, P., 2004; Bigiani, A. *et al.*, 2005; Boehm, T. and Zufall, F., 2006). Halpern M. and Martínez-Marcos A. (2003) have provided the most comprehensive review on structure and function of the vomeronasal system published thus far.

4.43.3 The Vomeronasal Organ

4.43.3.1 Basic Anatomical Organization

The structure of the VNO and its neuroepithelium has been described in representatives from virtually every major vertebrate class at the light microscopic and ultrastructural level, demonstrating a remarkable conservation between different species. Many of these original studies have been summarized by Halpern M. (1987) and Halpern M. and Martínez-Marcos A. (2003) and the reader is referred to these extensive reviews. In mammals, the VNO is a bilateral, cigar-shaped organ that is located at the base of the nasal septum, anterior and ventral to the main olfactory epithelium (Figures 1 and 2). Each VNO is encased in a bony and/or cartilaginous capsule known as vomer bone capsule. Chemosensory stimuli gain access to the VNO through its single rostral opening which, in rodents, opens into the nasal cavity. The main structural elements of the VNO are best seen in coronal sections (Figures 2(b)–2(d) and 2(h)) and include a central lumen, a medially located crescent-shaped sensory epithelium, and a laterally located nonsensory epithelium together with an extensive network of blood sinuses surrounded by a band of cavernous tissue. These latter components provide the hardware for a vomeronasal pump that aids in stimulus delivery (Meredith, M. and O'Connell, R. J., 1979; Meredith, M. *et al.*, 1980) (see below).

The VNO sensory epithelium consists primarily of three cell types (Ciges, M. *et al.*, 1977; Vaccarezza, O. L. *et al.*, 1981; Garrosa, M. and Coca, S., 1991):

1. elongated glia-like supporting cells,
2. bipolar sensory cells known as VSNs, and
3. a sparse population of basal stem cells.

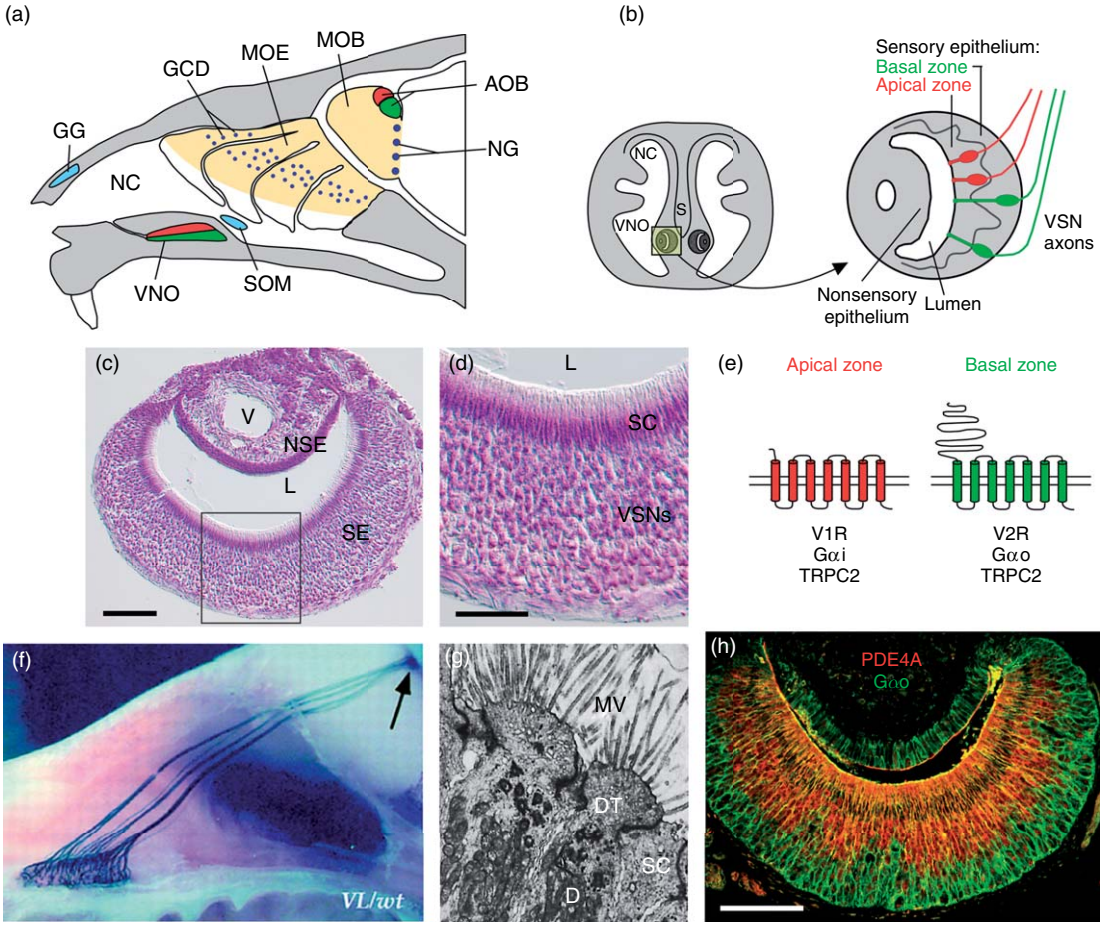

Figure 2 Organization of the sense of smell. (a) Midsagittal view of the rodent nasal cavity (NC) and forebrain. Vomeronasal sensory neurons (VSNs) in the vomeronasal organ (VNO), which is located at the base of the nasal septum (S), project to the anterior (red) or posterior (green) accessory olfactory bulb (AOB). Sensory neurons in the main olfactory epithelium (MOE) project their axons to glomeruli in the main olfactory bulb (MOB). These MOE neurons employ cyclic nucleotide-gated channels for sensory transduction. The septal organ of Masera (SOM) is an isolated island of olfactory sensory neurons that project axons to glomeruli in the ventromedial olfactory bulb. The Grüeneberg ganglion (GG) projects axons to specific glomeruli in the caudal region of the MOB. GCD (guanylyl cyclase D-expressing) neurons are located in the MOE, but project to a limited number of necklace glomeruli (NG) in the caudal MOB. (b–d) Coronal sectioning through the nasal cavity reveals the typical crescent-shaped organization of the VNO sensory epithelium (SE). The region delimited by the black box in (c) is shown at higher magnification in (d). L, lumen; NSE, nonsensory epithelium; SC, sustentacular cell; V, vein. Original sections in (c) and (d) are Nissl stains. Scale bars = 100 μm (c) and 50 μm (d). (e) The sensory epithelium is segregated into two distinct zones, both of which express a unique set of transduction-related molecules: (1) an apical zone (red VSNs) that expresses the G protein $G\alpha_{i2}$ as well as members of the V1R family of vomeronasal receptors, and (2) a basal zone that characteristically contains VSNs (green) that express $G\alpha_o$ and members of the V2R receptor family. Both neuron types express TRPC2. (f) Distribution and axonal projection pattern of a subpopulation of gene-targeted VSNs, showing that axon bundles (vomeronasal nerves) terminate in the AOB (arrow). To visualize this topography, a targeted mutation was generated that led to co expression of taulacZ in all VSNs expressing a distinct V1R receptor. (g) Electron micrograph of a transverse section through two mouse VSNs showing their dendritic process (D), which enlarges into a dendritic tip or knob (DT). From the knob emanate various microvilli (MV). (h) Visualization by confocal microscopy of the two principal expression zones of the VNO sensory epithelium using double-label immunohistochemistry with antibodies to phosphodiesterase type 4A (PDE4A, red) and $G\alpha_o$ (green). Scale bar = 100 μm. (a–e) Reprinted from Zufall, F., Ukhanov, K., Lucas, P., Liman, E., and Leinders-Zufall, T. 2005. Neurobiology of TRPC2: from gene to behavior. VSNs make up the majority of the cells in the sensory epithelium and are responsible for the detection of chemostimuli. VSNs extend a dendritic process to the luminal surface where it enlarges into an apical dendritic knob (Figure 2(g)). Unlike olfactory sensory neurons (OSNs), the dendritic knob of VSNs lacks cilia instead containing up to 100 microvilli (Figure 2(g)). In rat, VSN microvilli are 3–6 μm long and approximately 100 nm in diameter (Vaccarezza, O. L. *et al.*, 1981). The primary chemotransduction events are thought to take place in these microvilli. The most prominent feature of the dendritic knob is an extensive network of cisterns that appear as a series of small cylindrical rods without any specific orientation (Vaccarezza, O. L. *et al.*, 1981). Cisterns have not been detected in the microvilli. By contrast, the apical VSN dendrite has an extensive network of mitochondria and endoplasmic reticulum (Ciges, M. *et al.*, 1977; Vaccarezza, O. L. *et al.*, 1981). The mitochondria typically appear radially oriented in the dendrite and are generally parallel to the dendritic plasmalemma. The soma is characterized by its clear round nucleus and the extensive presence of rough endoplasmic reticulum. Particularly at the apical pole of the soma, where the dendrite begins to emerge, there is a complex stack of Golgi apparatus, rough endoplasmic reticulum, and a multivesicular body. Thus, organelles that could serve as intracellular Ca^{2+} stores are spatially compartmentalized in VSNs but, as far as we know, are not present in the microvilli. A single unmyelinated, axon emerges from the basal aspect of the soma of each VSN and exits the epithelium through the basal lamina. VSN axons coalesce to form the relatively long VNs that course along the septum, pass through the cribriform plate, and end in the glomeruli of the AOB, where they synapse onto second-order mitral cells (Halpern, M., 1987 and references therein). This axonal projection pattern is best observed in mutant mouse strains in which specific subpopulations of VSNs coexpress histological markers such as β-galactosidase or green fluorescent protein (Belluscio, L. *et al.*, 1999; Rodriguez, I. *et al.*, 1999) (Figure 2(f)).

The evolution of the VNO has been reviewed by Bertmar G. (1981) and Eisthen H. L. (1992; 1997). In general, the presence of a discrete VNO appears to be a derived character of tetrapods and did not arise as a terrestrial adaptation. VSNs are thought to first appear in amphibians, although a recent study using transgenic zebrafish in combination with VNO-specific markers showed the existence of a VNO-like subsystem of microvillous sensory neurons within the olfactory epithelium of fish (Sato, Y. *et al.*, 2005). Many reptiles possess a well-developed VNO; the VNO of the garter snake has become one of the best-studied model systems for understanding VNO function (Halpern, M. and Martinez-Marcos, A., 2003). The AOS has been lost independently in several taxa, including crocodilians, birds, some bats, and some primates (Eisthen, H. L., 1992). Among primates, New World monkeys possess VNOs whereas adult Old World monkeys do not appear to have well developed VNOs (Halpern, M. and Martinez-Marcos, A., 2003).

Do humans possess a functional VNO? While this question has been hotly debated for many years, a consensus is emerging (Meisami, E. and Bhatnagar, K. P., 1998; Trotier, D. *et al.*, 2000; Meredith, M., 2001; Dulac, C. and Torello, A. T., 2003; Halpern, M. and Martinez-Marcos, A., 2003; Wysocki, C. J. and Preti, G., 2004). At the anatomical level, bipolar receptor cells can be found within the VNO of the developing human fetus, but are absent in the adult (Boehm, N. and Gasser, B., 1993; Boehm, N. *et al.*, 1994; Wysocki, C. J. and Preti, G., 2004). More importantly, there appear to be no connections of the VNO with the adult brain, and in adult humans an anatomically distinct AOB cannot be located (Meisami, E. and Bhatnagar, K. P., 1998). Thus, any putative pheromonal responses by humans are likely mediated by the main olfactory system rather than by an AOS (Wysocki, C. J. and Preti, G., 2004). Consistent with a vestigial AOS in humans, most of the genes encoding vomeronasal classes of receptors are pseudogenes in humans (Dulac, C. and Torello, A. T., 2003).

4.43.3.2 Zonal Segregation of the Vomeronasal System

The VNO sensory epithelium of many mammals is not homogeneous, but it can be partitioned into at least two distinct zones or layers containing apical (superficial) and basal (deep) VSN populations, respectively (Halpern, M. *et al.*, 1998; Tirindelli, R. *et al.*, 1998; Dulac, C., 2000) (Figures 2(b), 2(e), and 2(h)). The two subsets of sensory neurons project their axons to segregated zones of the AOB (von Campenhausen, H. *et al.*, 1997; Mori, K. *et al.*, 2000; Halpern, M. and Martinez-Marcos, A., 2003). As will be summarized in subsequent sections of this chapter, it is becoming increasingly clear that this spatial segregation has important consequences for the handling of structurally and functionally

distinct sets of chemostimuli. The zonal separation was first recognized in the AOS of opossum, mouse, and rat by localization of the G protein subunits $G\alpha_{i2}$ and $G\alpha_o$ to two distinct zones: $G\alpha_{i2}$-positive VSNs define an apical zone whereas $G\alpha_o$-positive VSNs define a basal zone of the VNO epithelium (Halpern, M. *et al.*, 1995; Berghard, A. *et al.*, 1996; Jia, C. and Halpern, M., 1996) (Figures 2(e) and 2(h)).

As reviewed in detail by Halpern M. and Martínez-Marcos A. (2003), numerous other markers (often with unknown functions) are expressed in the VNO and AOB in a heterogeneous manner. For example, an axonal surface glycoprotein, olfactory cell adhesion molecule (OCAM), is expressed exclusively in apical VSNs (von Campenhausen, H. *et al.*, 1997; Yoshihara, Y. *et al.*, 1997). Likewise, the cAMP-specific phosphodiesterase type 4A (PDE4A) is found specifically in apical VSNs (Lau, Y. E. and Cherry, J. A., 2000) (Figure 2(h)). The axon guidance molecule neuropilin-2, a coreceptor for a subfamily of secreted guidance cues known as class 3 semaphorins, is also detected in VSNs of the apical layer (Walz, A. *et al.*, 2002). By contrast, olfactory marker protein (OMP), a 19 kDa cytoplasmic protein of unknown function, is usually present in all mature mammalian VSNs (Halpern, M. and Martinez-Marcos, A., 2003) (Figure 3(a)). Maybe most interestingly, the partitioning of the AOS is maintained at the level of different vomeronasal receptors, summarized in the next section.

4.43.3.3 A Genetic Basis for Stimulus Detection

Differential screening of cDNA libraries constructed from single rat VSNs led to the isolation of the first family of vomeronasal, G-protein-coupled receptor genes, the V1Rs (vomeronasal receptor family type 1) (Dulac, C. and Axel, R., 1995). These are completely distinct from the olfactory receptor superfamily. In the mouse genome, 293 V1R sequences have been identified of which 137 have uninterrupted full-length open reading frames. These are divided into 12 subfamilies that are considerably divergent from each other (Del Punta, K. *et al.*, 2000; Rodriguez, I. *et al.*, 2002). V1R genes are expressed in VSNs of the apical zone of the sensory epithelium (Figure 2(e)) and each individual receptor gene is expressed by only a small subset of VSNs (Dulac, C. and Axel, R., 1995) (Figures 3(b) and 3(c)). Evidence for a functional role of V1Rs in vomeronasal chemodetection comes from the observation that a mouse line lacking a cluster of V1Rs fails to respond to urinary chemicals with known pheromonal effects (6-hydroxy-6-methyl-3-heptanone, *n*-pentylacetate, and isobutylamine) (Del Punta, K. *et al.*, 2002a) (Figures 3(d) and 3(e)). In an alternative approach, green fluorescent protein-tagged VSNs that express the *V1rb2* gene have been shown to respond to the urinary compound 2-heptanone and this response was absent when *V1rb2* gene was deleted (Boschat, C. *et al.*, 2002). This result strongly implies that V1rb2 is a receptor for 2-heptanone.

A second large family of G-protein-coupled receptors expressed in the VNO is formed by the V2R (vomeronasal receptor family type 2) genes, which are expressed in VSNs of the basal zone (Herrada, G. and Dulac, C., 1997; Matsunami, H. and Buck, L. B., 1997; Ryba, N. J. and Tirindelli, R., 1997). With their large extracellular, N-terminal domain (Figure 2(e)), V2Rs resemble the calcium-sensing and metabotropic glutamate receptors rather than V1Rs and olfactory receptors. In the mouse, the V2R gene repertoire consists of 208 members of which only 61 exhibit an intact open reading frame (Yang, H. *et al.*, 2005). Although each V2R gene is generally expressed by only a small subset of VSNs, one subfamily of V2R genes is coexpressed broadly across basal VSNs (Martini, S. *et al.*, 2001). It still remains to be seen whether this results in the formation of functional homo- or heterodimeric receptor proteins (Bigiani, A. *et al.*, 2005).

VSNs in the basal layer express yet another multigene family representing nonclassical class Ib genes of the MHC (Ishii, T. *et al.*, 2003; Loconto, J. *et al.*, 2003). These seem to form multimolecular complexes with V2Rs and have been proposed to function as escort molecules in the transport of V2Rs to the cell surface (Loconto, J. *et al.*, 2003). These findings are intriguing in light of the evidence that subsets of basal VSNs are tuned to respond to class I MHC peptide ligands (Leinders-Zufall, T. *et al.*, 2004). However, a recent structural analysis of MHC class 1b proteins found no evidence for bound peptides, suggesting that class Ib molecules are unlikely to provide specific recognition of MHC peptide ligands in VSNs (Olson, R. *et al.*, 2005).

4.43.3.4 Molecular Physiology of Neuronal Sensing

Like OSNs, VSNs have evolved distinct ionic mechanisms that enable them to generate specific neural signals in response to chemostimulation. Recent years

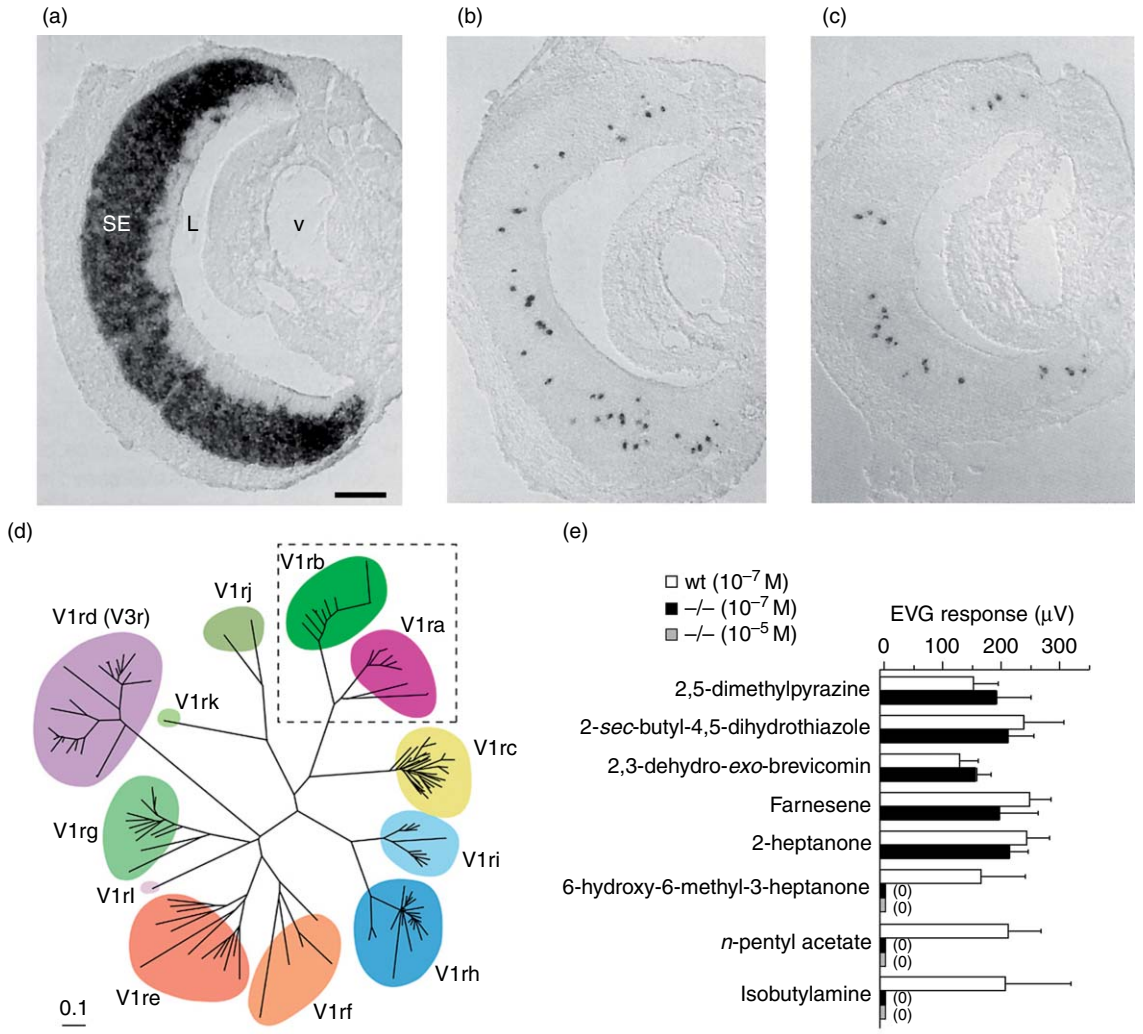

Figure 3 (a–c) Expression of Vr1 receptor RNA is restricted to a subset of vomeronasal sensory neurons (VSNs). Coronal sections of the vomeronasal organ (VNO) dissected from adult male rats were annealed with digoxigenin-labeled antisense RNA probes for olfactory marker protein (a). *In situ* hybridization to coronal sections of a dissected VNO using digoxigenin-labeled probes for rat Vr1 receptors VN1 (b) and VN3 (c). VNO cDNA clones 1 and 3 label 2.7% and 1.1% of cells in the rat sensory epithelium, respectively. L, lumen; SE, sensory epithelium; V, blood vessel. The two above-mentioned rat V1r genes have been predicted to belong to the V1ra group of vomeronasal receptors based on homology with the mouse V1r genes (Del Punta, K. *et al.*, 2000). (d) Unrooted tree representing the 137 mouse V1r genes, with 12 families readily distinguishable. Dashed lines enclose the V1ra and V1rb families of which most members were deleted from the germ line in the study shown in (e). (e) Histogram of electrovomeronasogram (EVG) responses (mean ± SD) from wild type (wt) and Δ*V1rab*Δ mutant mice. Both male and female mutant mice do not respond to 6-hydroxy-6-methyl-3-heptanone, *n*-pentyl acetate, and isobutylamine, but are otherwise normal in their responses to other tested compounds. This chemosensory deficiency supports a role of V1r receptors as pheromone receptors. Stimulus concentration, 10^{-7} M (white and black bars) or 10^{-5} M (gray bars). (a–c) Reprinted from Dulac, C. and Axel, R. 1995. A novel family of genes encoding putative pheromone receptors in mammals. Cell 83, 195–208, with permission from Elsevier. (d, e) reprinted from Del Punta, K., Leinders-Zufall, T., Rodriguez, I., Jukam, D., Wysocki, C. J., Ogawa, S., Zufall, F., and Mombaerts, P. 2002a. Deficient pheromone responses in mice lacking a cluster of vomeronasal receptor genes. Nature 419, 70–74, with permission from Nature Publishing Group.

have delivered significant progress in our ability to record physiological responses in VSNs and to analyze the ionic and molecular mechanisms underlying such responses.

Patch clamp recordings using individual VSNs from mouse, rat, frog, snake, turtle, or lizard – either freshly dissociated or in acute VNO tissue slices – have established that VSNs exhibit resting potentials,

ranging from −60 to −80 mV or even more negative (Trotier, D. *et al.*, 1993; Liman, E. R. and Corey, D. P. 1996; Trotier, D. and Doving, K. B., 1996; Inamura, K. and Kashiwayanagi, M., 2000; Taniguchi, M. *et al.*, 2000; Fadool, D. A. *et al.*, 2001; Fieni, F. *et al.*, 2003; Lucas, P. *et al.*, 2003; Leinders-Zufall, T. *et al.*, 2004; Labra, A. *et al.*, 2005). An electrogenic Na^+, K^+-ATPase appears to be essential in setting this resting potential (Trotier, D. and Doving, K. B., 1996). VSNs express a variety of voltage-dependent currents, including rapid, tetrodotoxin-sensitive Na^+ currents (Trotier, D. *et al.*, 1993; Liman, E. R. and Corey, D. P. 1996; Fieni, F. *et al.*, 2003), voltage- and Ca^{2+}-dependent K^+ currents (Trotier, D. *et al.*, 1993; Liman, E. R. and Corey, D. P., 1996; Inamura, K., *et al.*, 1997; Fadool, D. A. *et al.*, 2001; Labra, A. *et al.*, 2005), several types of voltage-activated Ca^{2+} currents (Trotier, D. *et al.*, 1993; Liman, E. R. and Corey, D. P., 1996; Fieni, F. *et al.*, 2003), and hyperpolarization-activated inward rectifying currents (Trotier, D. *et al.*, 1993; Liman, E. R. and Corey, D. P., 1996). A common feature of most VSNs analyzed thus far seems to be their high input resistance. Combined with a low threshold for action potential generation, this means that only a few picoampere of inward current are sufficient to evoke repetitive spiking in these neurons (Liman, E. R. and Corey, D. P., 1996; Inamura, K., *et al.*, 1997; Trotier, D., 1998; Taniguchi, M. *et al.*, 2000), an ability that has important consequences for the generation of ligand-induced responses in these cells. The biophysical features of VSNs differ considerably from those observed in supporting cells of the vomeronasal epithelium (Ghiaroni, V. *et al.*, 2003).

How do VSNs respond to chemical stimulation? Several laboratories used extracellular or whole-cell current clamp recordings to demonstrate that VSNs, at rest, maintain a relatively low spiking activity and that chemostimulation produces a transient increase in the rate of action potential firing (Trotier, D., 1998; Inamura, K. *et al.*, 1999; Holy, T. E. *et al.*, 2000; Leinders-Zufall, T. *et al.*, 2000; Lucas, P. *et al.*, 2003; Leinders-Zufall, T. *et al.*, 2004) (Figures 4(a) and 4(b)). This excitation is caused by the generation of a depolarizing receptor potential sufficient in size to activate voltage-gated Na^+ channels (Lucas, P. *et al.*, 2003) (Figure 4(c)). The ionic properties of this receptor potential are not yet fully understood, but it is clear that the receptor potential depends critically on the generation of a transient inward current in the distal dendrites and microvilli of VSNs which is associated with an increase in membrane conductance (Inamura, K. and Kashiwayanagi, M., 2000; Taniguchi, M. *et al.*, 2000; Lucas, P. *et al.*, 2003) (Figure 4(d)). The primary electrical events in VSN dendrites can also be monitored by placing micropipettes on VSN microvilli using a semi-intact VNO preparation and recording local field potentials that are known as an electrovomeronasogram (EVG) (Figures 4(e) and 4(f)). This technique has been very useful in the search for molecular cues acting on VSNs (Taniguchi, M. *et al.*, 1998; Leinders-Zufall, T. *et al.*, 2000; 2004) (Figure 4(f)), as well as for the phenotypic characterization of VSN responses in animals with targeted mutations (Del Punta, K. *et al.*, 2000; Leypold, B. G. *et al.*, 2002) (Figures 3(e) and 5(f)). Finally, it is important to note that chemostimulation also causes a transient rise in the intracellular Ca^{2+} concentration of VSNs (Leinders-Zufall, T. *et al.*, 2000; Cinelli, A. R. *et al.*, 2002; Spehr, M. *et al.*, 2002; Leinders-Zufall, T. *et al.*, 2004) (Figures 4(g) and 4(h)). This stimulus-evoked Ca^{2+} response is used increasingly to identify molecular cues recognized by the VSNs and to determine VNO coding mechanisms (Figure 4(i) and see below).

Although these basic response properties have now been observed independently by several investigators, other experiments suggest that there are also differences in the properties of VSN sensory responses amongst species. For example, VSNs from turtle and lizard, respectively, have been shown to exhibit both inward and outward currents in response to chemostimulation (Fadool, D. A. *et al.*, 2001; Labra, A. *et al.*, 2005). In particular, the properties of the voltage-activated K^+ currents differ between VSNs from male and female animals (Fadool, D. A. *et al.*, 2001). Thus, a modicum of caution needs to be used for extrapolating cellular mechanisms in response to chemostimulation across species.

4.43.3.5 Signal Transduction Mechanisms

How do VSNs transduce a sensory stimulus into a change in membrane conductance? Increasing evidence indicates that this process depends on a G-protein-coupled second messenger cascade that ultimately leads to the activation of specific ion channels. Here, we will summarize the key results that led to our current understanding of this signaling cascade (Halpern, M. and Martinez-Marcos, A., 2003; Bigiani, A. *et al.*, 2005; Zufall, F. *et al.*, 2005).

An important development during the mid 1990s was the demonstration that VSNs and OSNs differ in their chemosensory signal transduction pathways. Several molecules that are essential for transduction

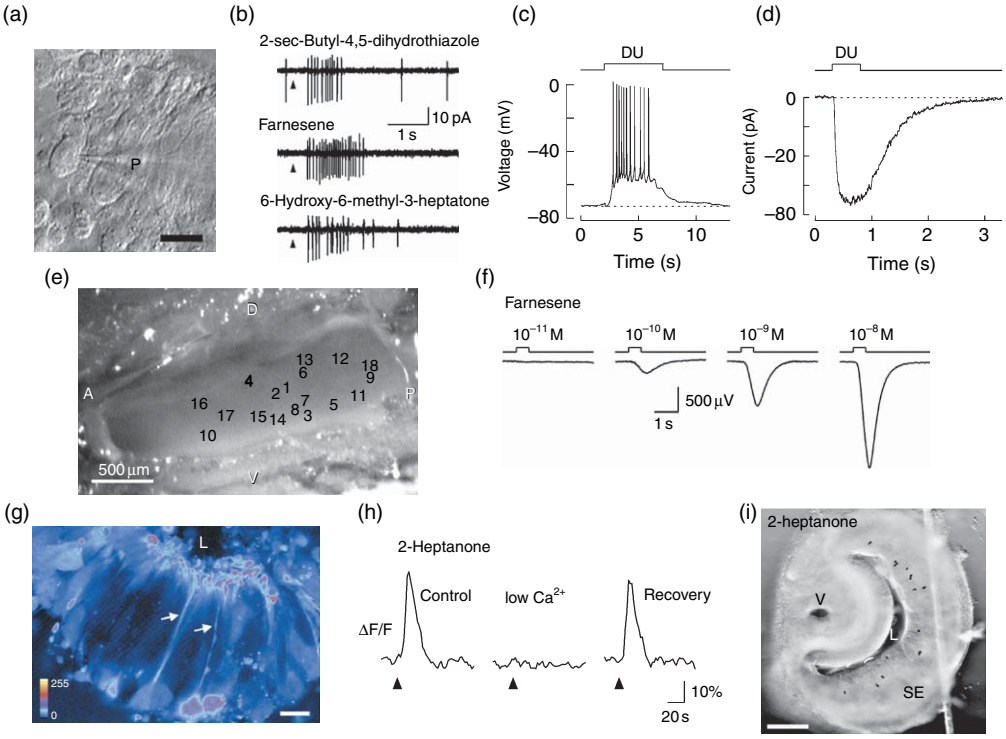

Figure 4 (a) Infrared–differential interference contrast micrograph showing a vomeronasal organ (VNO) tissue slice. Individual vomeronasal sensory neuron (VSN) somata are clearly visible. P, patch electrode. Scale bar = 10 µm. (b) Trains of extracellularly recorded, action-potential-driven, capacitive currents produced by bath application of 2-*sec*-butyl-4,5-dihydrothiazole, farnesene, or 6-hydroxy-6-methyl-3-heptanone (all at 10^{-7} M). Each response was from a different vomeronasal sensory neuron (VSN) using the approach shown in (a). Arrowheads, start of bath application (duration, 1–3 s). (c) Focal stimulation of a current-clamped VSN with dilute urine (DU) produces a depolarizing receptor potential leading to robust action potential discharges. (d) Under voltage clamp, 500-ms stimulation generates a rapidly activating and then deactivating inward current (the sensory current). Holding potential, −70 mV. (e, f) Image and electrovomeronasogram (EVG) responses of the microvillus surface of the vomeronasal sensory epithelium. Numbers in the image indicate the various sites at which field potentials (EVG responses) were recorded. 500-ms pulses of increasing concentrations of farnesene produced dose-dependent EVG responses. Ligands were focally applied to the microvillus surface of the sensory epithelium by a multibarreled stimulation pipette. A, anterior; D, dorsal; V, ventral; P, posterior. (g, h) Pheromone-induced Ca^{2+} elevations in single VSNs. (g) Confocal fluorescence image acquired at rest (pseudocolor scale) showing subcellular structures of VSNs such as single dendrites. Scale bar = 10 µm. (h) Waveform of somatic Ca^{2+} transient of a single VSN evoked by bath-applied 2-heptanone (10^{-7} M). The response was reversible abolished by lowering the Ca^{2+} concentration in the bath solution. (i) Spatial representation of functional, pheromone-induced activity in VNO. Reconstructed VSN response map ($\Delta F/F$ Ca^{2+} images digitally superimposed onto transmitted light image of the same slice) for 10^{-7} M 2-heptanone, showing that VSNs activated by this ligand (black dots) were interspersed within the apical zone of the sensory epithelium (SE). L, lumen; V, vein. Scale bar = 100 µm. (a, b, f, g, h, i) Reprinted from Leinders-Zufall, T., Lane, A. P., Puche, A. C., Ma, W., Novotny, M. V., Shipley, M. T., and Zufall, F. 2000. (c, d) Reprinted from Lucas, P., Ukhanov, K., Leinders-Zufall, T., and Zufall F. 2003. A diacylglycerol-gated cation channel in vomeronasal neuron dendrites is impaired in *TRPC2* mutant mice: mechanism of pheromone transduction. Neuron 40, 551–561, with permission from Elsevier. (e) Reprinted from Zufall, F., Kelliher, K. R., and Leinders-Zufall, T. 2002. Pheromone detection by mammalian vomeronasal neurons. Microsc. Res. Tech. 58, 251–260, with permission of Wiley.

in OSNs – the G protein G_{olf}, adenylyl cyclase type III, and the cyclic nucleotide-gated channel type A2 (CNGA2) subunit – are not present in the VNO sensory epithelium (Berghard, A. *et al.*, 1996; Wu, Y. *et al.*, 1996). Unlike OSNs, VSNs do not respond to cyclic nucleotides with a conductance change or Ca^{2+} rise (Liman, E. R. and Corey, D. P., 1996; Cinelli, A. R. *et al.*, 2002; but see also Taniguchi, M. *et al.*, 1996). The focus of interest therefore shifted toward the other major family of ion channels involved in sensory signal transduction, the transient receptor potential (TRP) channels. An important

advance came with the cloning of *TRPC2* from bovine, mouse, and rat (Wissenbach, U. *et al.*, 1998; Liman, E. R. *et al.*, 1999; Vannier, B. *et al.*, 1999; Hofmann, T. *et al.*, 2000). Because *TRPC2* encodes a protein that is expressed in all VSNs and specifically localized to the sensory microvilli of these cells (Figures 5(a) and 5(b)), it was proposed to participate in VSN sensory transduction (Liman, E. R. *et al.*, 1999; Menco, B. P. *et al.*, 2001). Many TRP channels, especially those of the classical TRPC subfamily, are known to depend on signaling pathways involving phospholipase C (PLC), an enzyme that hydrolyzes phosphatidylinositol-4,5-bisphosphate (PIP_2) into inositol 1,4,5-trisphosphate ($Ins(1,4,5)P_3$) and diacylglycerol (DAG) (Montell, C. *et al.*, 2002). Therefore, the localization of TRPC2 to VSN microvilli

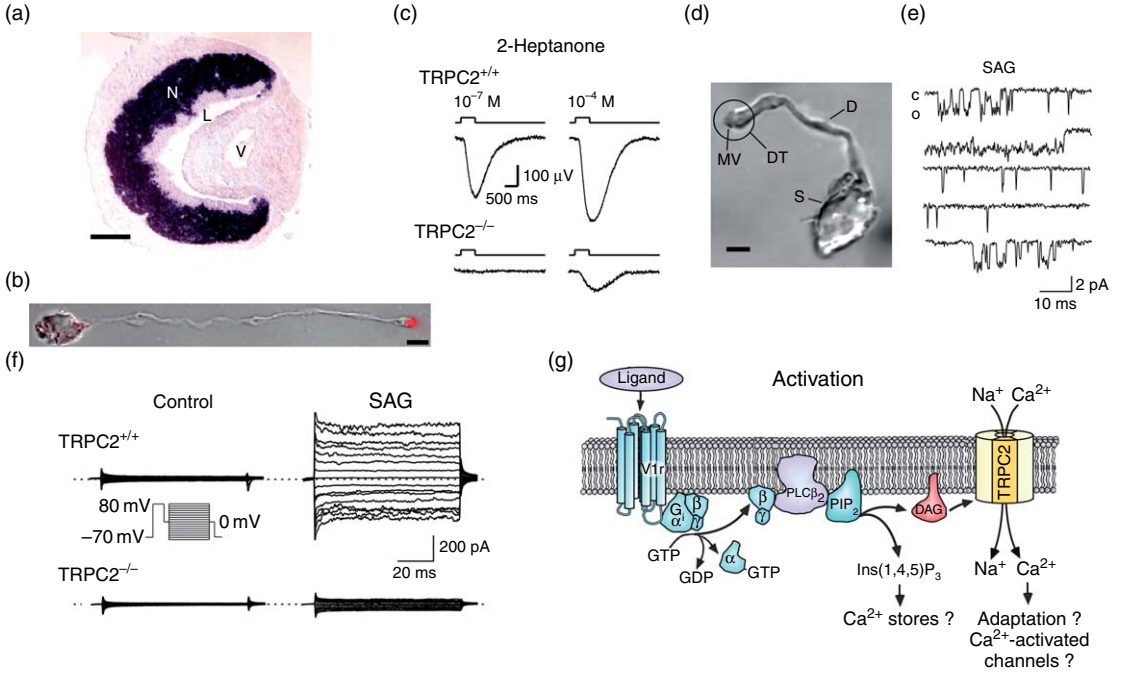

Figure 5 (a) Expression of TRPC2 in the vomeronasal organ (VNO). Labeling of a section of VNO from adult rat with a digoxigenin antisense probe directed against TRPC2 reveals strong expression (dark reaction product) of the TRPC2 mRNA in all VSNs (N). Scale bar = 100 μm. (b) In a singly dissociated vomeronasal sensory neuron (VSN), TRPC2 immunoreactivity (red) is clearly seen in the tuft of microvilli at the distal end of the dendrite. Scale bar = 5 μm. (c) Strongly diminished responses are observed in $TRPC2^{-/-}$ VSNs to 2-heptanone. Representative field potential responses from wild-type ($TRPC2^{+/}$) (upper) and $TRPC2^{-/-}$ mice (lower). Responses were induced by 500 ms pulses of 2-heptanone at 10^{-7} or 10^{-4} M, respectively. (d) Micrograph showing an isolated mouse VSN. D, dendrite; MV, microvilli; S, soma. Plasma membrane inside out patches were taken from the encircled area denoted as dendritic tip (DT) in experiments shown in (e). Scale bar = 3 μm. (e) The endogenous diacylglycerol analog 1-stearoyl-2-arachidonoyl-*sn*-glycerol (SAG) activates a 42-pS channel. Control recordings before SAG application showed no activity or only an occasional brief channel opening. Continuous application of SAG (10 μM) evoked single-channel events. (f) $TRPC2^{-/-}$ VSNs display a striking defect in the activation of the diacylglycerol-gated channel. Representative families of whole-cell currents to a series of depolarizing and hyperpolarizing voltage steps (as indicated in the figure) were recorded from an isolated wild-type (upper) and $TRPC2^{-/-}$ VSN (lower). VSNs were exposed successively to extracellular solution (control) and solution containing SAG (50 μM). Voltage-gated channels were blocked in these experiments. Dotted line, zero current level. (g) Schematic representation of pathways that might regulate the activity of the TRPC2 channel in the DT of a mammalian VSN. The model refers to VSNs of the apical zone of the VNO. Whether this applies also to VSNs of the basal zone remains to be investigated. (a, b) Reprinted from Liman, E. R., Corey, D. P., and Dulac, C. 1999. suggested the use of a phosphoinositide signaling pathway for VSN transduction (Liman, E. R. *et al.*, 1999). Several studies have now provided evidence that PLC is indeed critical for the generation of sensory responses in VSNs (Inamura, K. *et al.*, 1997; Holy, T. E. *et al.*, 2000; Lucas, P. *et al.*, 2003).

Investigations of mice with targeted deletions in *TRPC2* have established an essential role of this gene in the detection of pheromonal stimuli by the VNO (Leypold, B. G. *et al.*, 2002; Stowers, L. *et al.*, 2002). In $TRPC2^{-/-}$ mice, pheromone-evoked EVG responses were either absent or strongly diminished, depending on stimulus concentration (Leypold, B. G. *et al.*, 2002) (Figure 5(c)). Likewise, action potential recordings showed that VSNs from $TRPC2^{-/-}$ mice are unable to respond to cues present in dilute urine (Stowers, L. *et al.*, 2002). Furthermore, $TRPC2^{-/-}$ mice showed striking defects in social behaviors (Leypold, B. G. *et al.*, 2002; Stowers, L. *et al.*, 2002), results that will be discussed in Section 4.43.5.

What kind of ion channel is formed by TRPC2? Although this question is still being investigated, evidence indicates that TRPC2 is required for a Ca^{2+}-permeable cation channel that is gated by the lipid messenger DAG or one of its endogenous analogs (Lucas, P. *et al.*, 2003). Excised patch recordings identified a 42-pS DAG-activated cation channel present in high density in the plasma membrane of dendritic knobs of VSNs and the activation of this channel is strongly defective in $TRPC2^{-/-}$ VSNs (Figures 5(d)–5(f)). Furthermore, the functional properties of this channel are consistent with those of the pheromone-evoked conductance (Lucas, P. *et al.*, 2003). Independent evidence that endogenously produced DAG may be a critical second messenger in the sensory response of VSNs comes from pharmacological blockade of DAG kinase, an enzyme involved in termination of DAG signaling (Lucas, P. *et al.*, 2003; Zufall, F. *et al.*, 2005). Thus a direct link between stimulus-induced PLC activity, gating of the TRPC2 channel by DAG, and the sensory current has been established (Figure 5(g)).

Several other second messengers such as Ca^{2+} or $Ins(1,4,5)P_3$ are likely to be involved in VSN signal transduction (Cinelli, A. R. *et al.*, 2002; Lucas, P. *et al.*, 2003). TRPC2 seems to form protein–protein interactions with the type III $Ins(1,4,5)P_3$ receptor (Brann, J. H. *et al.*, 2002) and biochemical studies in several species have reported increased $Ins(1,4,5)P_3$ levels in response to sensory stimulation of the VNO (Luo, Y. *et al.*, 1994; Kroner, C. *et al.*, 1996; Wekesa, K. S. and Anholt, R. R., 1997; Krieger, J. and Breer, H., 1999; Sasaki, K. *et al.*, 1999; Cinelli, A. R. *et al.*, 2002). Furthermore, flash photolysis of $Ins(1,4,5)P_3$ has been shown to excite frog VSNs (Gjerstad, J. *et al.*, 2003). One possibility is that $Ins(1,4,5)P_3$-induced Ca^{2+} release from intracellular stores (Lucas, P. *et al.*, 2003) leads to the opening of Ca^{2+}-dependent channels. These could be Ca^{2+}-activated cation channels, such as those found in hamster VSNs (Liman, E. R., 2003), or other Ca^{2+}-dependent channels. Such a mechanism could be involved in the primary sensory response, or it could mediate further amplification of this response. Even less clear than the roles of $Ins(1,4,5)P_3$ and Ca^{2+} are the proposed roles for arachidonic acid (Spehr, M. *et al.*, 2002) and cAMP (Halpern, M. and Martinez-Marcos, A., 2003) in VSN transduction. More information will be required to assess the precise function of these messenger molecules.

4.43.3.6 The Search for Sensory Stimuli

Understanding the functional role of the AOS requires identification of the sensory cues that are detected by the VSNs. It has been known since the 1970s that the mammalian VNO plays an essential role in the detection of stimuli of social nature, including some pheromone-like signals (Meredith, M. *et al.*, 1983; Halpern, M., 1987; Johnston, A. N. *et al.*, 1993); however, identification of the molecular nature of these stimuli proved surprisingly difficult. The advent of large-scale neurophysiological recording techniques in the VNO and AOB has enabled a more systematic search for vomeronasal stimuli. Surprisingly, the long held notion that VSNs detect only nonvolatile molecules appears an oversimplification of the systems function. VSNs show responses to a wider range of stimuli, including molecules that would not normally be categorized as pheromones. Additionally, it is now clear that many social recognition signals including some pheromones can also be detected by OSNs in the main olfactory system and that the mammalian main and AOSs detect, in part, overlapping sets of stimuli. Putatively, information about the same stimuli derived from each system is integrated in higher brain centers (Meredith, M., 1998; Boehm, T. and Zufall, F., 2006; Boehm, U. *et al.*, 2005; Shepherd, G. M., 2006; Spehr, M. *et al.*, 2006).

4.43.3.6.1 Stimulus access

Abundant evidence has shown that animals must actively enlarge the openings to the VNO and activate a pumping or suction mechanism to transport

chemical stimuli into the lumen of the VNO (Halpern, M., 1987; Wysocki, C. J. and Meredith, M., 1987). Work by Meredith and coworkers in hamster has established that the large blood vessels located within the VNO are capable of dilation and constriction and thus serve as a pumping mechanism that is activated in situations of novelty (Meredith, M., 1994). This vascular pump is under the control of sympathetic nerve fibers and interruption of these efferent nerves causes behavioral deficits similar to those produced by lesioning of the VNs (Meredith, M. and O'Connell, R. J., 1979; Meredith, M. *et al.*, 1980; Meredith, M. and O'Connell, J. M., 1988). There is now excellent evidence that activation of the VNO by appropriate stimuli can occur following direct physical contact of the nose with a stimulus source (Luo, M. *et al.*, 2003; Leinders-Zufall, T. *et al.*, 2004). Recordings from single neurons in the AOB of mice that were engaged in natural behaviors showed increased neuronal firing after physical contact with a conspecific (Luo, M. *et al.*, 2003) (see also Section 4.43.4). For nonvolatile cues such as peptide ligands, such physical contact is indeed required to reach sensory neurons in the nose in an *in vivo* situation (Leinders-Zufall, T. *et al.*, 2004; Spehr, M. *et al.*,2006). Volatile cues dissolved in bodily secretions will also reach the VNO following direct physical contact between the nose and a stimulus source. However, whether the VNO can detect such volatiles in the absence of direct physical contact remains debated (Luo, M. *et al.*, 2003; Trinh, K. and Storm, D. R., 2003). In at least one example, clear activation of the mouse AOB in vivo was observed in response to volatile stimuli that were delivered via the airstream (Xu, F. *et al.*, 2005).

4.43.3.6.2 Complex stimuli

To evoke sensory responses in the AOS, numerous researchers have tested complex natural communication stimuli such as urine, soiled bedding, vaginal secretion, and seminal fluid. Functional responses to these stimuli were monitored using a variety of techniques including immediate early gene expression in VNO and AOB (Halem, H. A. *et al.*, 1999; Kumar, A. *et al.*, 1999; Halem, H. A., *et al.*, 2001) or medial amygdala (Meredith, M. and Westberry, J. M., 2004), biochemical analysis of second messenger formation in VNO tissue (Wekesa, K. S. and Anholt, R. R., 1997), electrophysiological recording or Ca^{2+} imaging from single neurons in the VNO (Inamura, K. *et al.*, 1999; Holy, T. E. *et al.*, 2000; Spehr, M. *et al.*, 2002; Leinders-Zufall, T. *et al.*, 2004) or AOB (Luo, M. *et al.*, 2003), and functional magnetic resonance imaging (fMRI) of AOB (Xu, F. *et al.*, 2005). Although the details of the findings in these studies differ in many cases, taken together the evidence clearly shows that complex stimuli contain specific molecular cues that are recognized by VSNs. Particularly interesting data from single cell VSN recordings suggest that VSNs respond to cues present in urine that carry information about strain, species, and sex (Inamura, K. *et al.*, 1999; Holy, T. E. *et al.*, 2000). Recordings from single AOB neurons of freely behaving mice led to similar conclusions regarding the information content of vomeronasal stimuli (Luo, M. *et al.*, 2003). These latter authors also showed for the first time neuronal activity in response to active social investigation of anogenital or head/face regions of conspecifics of different genetic strains (Luo, M. *et al.*, 2003).

4.43.3.6.3 Urinary volatiles

Mouse urine contains hundreds of volatile compounds (Schwende, F. J. *et al.*, 1986; Novotny, M. V. *et al.*, 1999a) some of which have been associated with distinct endocrine or behavioral responses in conspecifics and are therefore considered prospective pheromones (see Section 4.43.5). A direct demonstration that at least some of these molecules directly activate VSNs came from a combination of EVG recording and Ca^{2+} imaging in VNO slices (Leinders-Zufall, T. *et al.*, 2000). The putative mouse pheromones 2,5-dimethylpyrazine, 2-*sec*-butyl-4,5-dihydrothiazole, 2,3-dehydro-*exo*-brevicomin, a mixture of E,E-α-farnesene and E-β-farnesene (referred to as farnesene), 2-heptanone, and 6-hydroxy-6-methyl-3-heptanone were potent sensory cues in the mouse VNO (Table 1) (Leinders-Zufall, T. *et al.*, 2000). VSNs responded to these compounds at nanomolar to subnanomolar concentrations, several orders of magnitude more sensitive than previously suspected. Activated VSNs were located in the apical, V1R-expressing layer of the VNO (Leinders-Zufall, T. *et al.*, 2000) (Figure 4(i)). Several other urinary volatiles including *n*-pentyl acetate and isobutylamine (Del Punta, K. *et al.*, 2002a; Trinh, K. and Storm, D. R., 2003) were subsequently identified as stimuli for mouse VSNs. Genetic ablation of a group of V1R genes showed an essential role for these receptors in the detection of 6-hydroxy-6-methyl-3-heptanone, *n*-pentyl acetate, isobutylamine, and 2-heptanone (Boschat, C. *et al.*, 2002; Del Punta, K. *et al.*, 2002a). Further evidence for the activity of these molecules derives from functional imaging in the AOB of intact mice showing that 2-heptanone activates the AOS (Xu, F. *et al.*, 2005).

Table 1 Structure, origin, and function of some urinary volatiles acting in the VNO

Name	*Chemical structure*	*Origin*	*Possible chemosignaling function in female mice*	*Detection threshold EVG response (M)*
2,5-Dimethylpyrazine		Female urine	Puberty delay[a]	10^{-8}–10^{-7}
2-*sec*-Butyl-4,5-dihydrothiazole		Male bladder, urine	Estrus synchronization[b], puberty acceleration[c]	10^{-10}–10^{-9}
2,3-Dehydro-*exo*-brevicomin		Male bladder, urine	Estrus synchronization[b], puberty acceleration[c]	10^{-10}–10^{-9}
α- and β-farnesenes		Male preputial gland	Puberty acceleration[c]	10^{-11}–10^{-10}
2-Heptanone		Female or male urine	Estrus extension[d]	10^{-11}–10^{-10}
6-Hydroxy-6-methyl-3-heptanone		Male bladder urine	Puberty acceleration[e]	10^{-8}–10^{-7}

4.43.3.6.4 General odors

Early studies indicated that VSNs are activated by a fraction of odorants without known pheromonal functions (Müller, W., 1971; Tucker, D., 1971). More recent investigations have confirmed and extended these findings (Sam, M. *et al.*, 2001; Trinh, K. and Storm, D. R., 2003). Functional imaging studies of the AOB used a mixture of six of the compounds reported by Sam M. *et al.* (2001) – methyl anisole, patchone, indole, helional, butyrophenone, and fenchone – to demonstrate that they stimulate the mouse AOB *in vivo* (Xu, F. *et al.*, 2005). Sam M. *et al.* (2001) suggested that these odorants could be released from plants or other animal species that may signal the presence of a predator or indicate the suitability of a particular site for feeding or nesting.

4.43.3.6.5 Major histocompatibility complex peptide ligands

A particularly surprising finding was the discovery that subsets of mouse VSNs are tuned to recognize members of a large family of immune system molecules known as the MHC peptide ligands (Leinders-Zufall, T. *et al.*, 2004). Together with the evidence presented above, this demonstrates that the mouse VNO can detect both volatile and nonvolatile cues. As pointed out by Boehm T. and Zufall F. (2006), MHC peptides are not considered pheromones according to the classical definition by Karlson P. and Lüscher M. (1959). Hence, the detection of MHC peptide ligands by VSNs shows that the VNO also plays important roles in the sensing of nonpheromonal chemical signals of social nature.

Table 2 Structure of peptide ligands acting in the VNO

MHC peptide ligands	*Other specific peptides*
AAPDNRETF[a]	SIPSKDALLK (sodefrin)[b]

MHC, major histocompatibility complex; VNO, vomeronasal organ.

Immune system researchers have established a clear structural relationship between MHC molecules and their peptide ligands, which are usually nine amino acids long (Table 2; summarized in Boehm T. and Zufall F. 2006). MHC/peptide complexes present at the cell surface carry information about the genetic makeup of cells. They are shed from the cell surface and their fragments appear in bodily fluids such as serum, saliva, sweat, and urine (Singh, P. B. *et al.*, 1987). These truncated MHC molecules are thought to have a reduced affinity to their peptide ligands and are thus likely to release them into the extracellular space. The finding that the structural complexity of MHC peptide ligands can be sensed by neurons in the VNO suggests that this information is used for the sensory evaluation of the genotype of a conspecific, or in other words for the detection of genetic individuality (Boehm, T. and Zufall, F., 2006). Experiments in behaving mice strongly support this notion (Leinders-Zufall, T. *et al.*, 2004) (see Section 4.43.5). VSNs can sense MHC peptides at low concentrations, with detection thresholds near 10^{-12} M. Mapping studies in VNO slices combined with the use of immunocytochemical markers showed that MHC peptides are detected by VSNs in the basal layer (Leinders-Zufall, T. *et al.*, 2004). This indicates that VSNs of the apical and basal zones detect structurally and functionally distinct sets of molecular cues.

4.43.3.6.6 Other specific peptides

It is worth noting that a number of specific peptide pheromones have been identified previously in organisms as diverse as bacteria, fungi, mollusks, arthropods, and a variety of vertebrates (Altstein, M., 2004). Among vertebrates, maybe the best example comes from work in closely related newt species where the decapeptides sodefrin (SIPSKDALLK) and silefrin (SILSKDAQLK) have been shown to attract conspecific females (Kikuyama, S. *et al.*, 1995; Yamamoto, K. *et al.*, 2000) (Table 2), most likely via activation of their VNOs (Toyoda, F. and Kikuyama, S., 2000). More recently, in mice a male-specific 7 kDa peptide secreted from the extraorbital lacrimal gland has been shown to stimulate VSNs (Kimoto, H. *et al.*, 2005). This peptide (Table 2), which has been called exocrine gland-secreting peptide 1 (ESP1), seems to be encoded by a gene from a new multigene family consisting of at least 23 members (Kimoto, H. *et al.*, 2005). Although the behavioral role of ESP1 is not yet clear, these results together with those of Leinders-Zufall T. *et al.* (2004) indicate that social communication in mammals involves the detection of extended families of peptidergic chemosignals by the VNO.

4.43.3.6.7 Proteins

It has long been thought that VSNs can detect chemical signals of proteinaceous nature. The best evidence for protein detection by the VNO comes from work using snakes (Jiang, X. C. *et al.*, 1990; summarized in Halpern, M. and Martinez-Marcos, A., 2003) where a 20-kDa chemoattractant purified from earthworm shock secretions (known as ES20) has been shown to induce excitatory responses in VNO and AOB. This protein has been used extensively to characterize second messenger formation and signal transduction events in snake VSNs (Halpern, M. and Martinez-Marcos, A., 2003). Collectively, this work has shown that prey detection is a major function of the snake VNO. In a terrestrial salamander, a 22 kDa protein with structural homology to members of the interleukin-6 cytokine family has been shown to affect female receptivity but it is not yet clear whether this molecule is detected by the VNO (Rollmann, S. M. *et al.*, 1999).

Work in rodents also suggested an involvement of proteins in VNO sensing. Mouse urine contains a class of highly polymorphic proteins known as major urinary proteins (MUPs) that are implicated in individuality recognition (Hurst, J. L. *et al.*, 2001). It seems clear that MUPs bind urinary volatiles (Novotny, M. V. *et al.*, 1999a; Zidek, L. *et al.*, 1999) and release them from scent marks (Hurst, J. L. and Beynon, R. J., 2004). However, whether MUPs

devoid of their volatile ligands function as VSN stimuli as suggested by Mucignat-Caretta C. *et al.* (1995) and Cavaggioni A. and Mucignat-Caretta C. (2000) remains on open question (see Novotny, M. V. *et al.*, 1999a). Essentially, the same can be said about a protein isolated from hamster vaginal fluid known as aphrodisin (Singer, A. G. *et al.*, 1986). Like MUPs, aphrodisin belongs to the lipocalin superfamily and it remains unclear whether it functions as a carrier for small hydrophobic chemicals or as a pheromone in its own right (Briand, L. *et al.*, 2004a; 2004b).

4.43.3.7 Sensory Coding Strategies in the Vomeronasal Organ

In the main olfactory system, our current understanding is that OSNs respond to chemical epitopes that may be present on different odorant molecules, and that the tuning of main olfactory neurons is broad; that is, a single OSN responds to related chemical epitopes with different affinities. By contrast, mouse VSNs – at least those located in the apical layer of the VNO – show much narrower tuning properties. Specifically, VSN tuning curves to putative pheromone molecules do not seem to broaden with increasing concentrations of ligand and an increase in stimulus strength does not recruit activation of more neurons (Leinders-Zufall, T. *et al.*, 2000). Populations of VSNs also exhibit strong selectivity for either male or female urine, although the molecules underlying this response are unknown (Holy, T. E. *et al.*, 2000). Thus, if OSNs in the MOE are hypothesized to be epitope sensors, VSNs of the apical zone might be considered molecule detectors for single putative pheromones. However, not all VSNs in apical and basal zones may employ the same strategies for encoding socially relevant chemosignals. For example, work using the MHC peptide ligands as sensory stimuli has clearly shown that a given basal VSN can detect multiple peptides exhibiting distinct chemical structures (Leinders-Zufall, T. *et al.*, 2004). Furthermore, the vast structural repertoire of the family of MHC peptide ligands argues against a one cell–one receptor–one ligand strategy but rather for the existence of some kind of combinatorial coding mechanism in peptide-detecting VSNs. Thus, mammalian VSNs may employ a variety of coding strategies. Similar conclusions were reached by analyzing sensory responses to complex stimuli from lizard VSNs (Labra, A. *et al.*, 2005).

4.43.4 The Accessory Olfactory Bulb

4.43.4.1 Inputs from the Vomeronasal Organ

VSNs within the VNO project axons that traverse along the nasal septum, through the cribriform plate, along the medial surface of the main olfactory bulb (MOB), and terminate exclusively in the AOB (Figure 2(f)). In rodents, the AOB is located at a dorsocaudal position relative to the MOB (Figures 1(a), 2(a), and 2(f)). The fascicles of axons comprising this VN are distinct from those fascicles innervating the MOB (Halpern, M., 1987). These axons pass through the nerve fiber layer (aONL) of the AOB and converge to glomeruli in the accessory glomerular layer (aGL) (Figure 6). Unlike the MOB where glomeruli are large (50–100 μm diameter) and organized into a distinct layer one to two glomeruli thick segregated by numerous juxtaglomerular cells, AOB glomeruli are smaller (10–50 μm diameter), numerous, poorly separated by juxtaglomerular cells, and distributed in a loosely organized layer that is many glomeruli thick. Early studies using cell surface antigens showed that the projections from the VNO segregated into two zones, an anterior and a posterior zone (Mori, K. *et al.*, 1985; Mori, K., 1987; Schwarting, G. A. and Crandall, J. E., 1991; Takami, S. *et al.*, 1992b; Osada, T. *et al.*, 1994). Recent studies demonstrated that these anterior and posterior zones receive input from distinct classes of VSNs (Halpern, M. *et al.*, 1995; Rodriguez, I. *et al.*, 1999; Del Punta, K. *et al.*, 2002b). VSNs located apically in the VNO sensory epithelium expressing the V1R receptor family and the G protein $G\alpha_{i2}$ (described above) project to the anterior aGL domain, while VSNs located basal expressing the V2R receptor family and the $G\alpha_o$ G protein project axons into the posterior aGL domain.

In the main olfactory system, OSNs expressing the same odor receptor gene project to only two or a few glomeruli in each bulb (Rodriguez, I. *et al.*, 1999; Del Punta, K. *et al.*, 2002b). However, unlike the high degree of axon convergence in the MOB, VSNs expressing the same receptor gene project to multiple glomeruli in either the anterior or posterior domain of the AOB (six to 20 glomeruli per gene have been reported; Belluscio, L. *et al.*, 1999; Rodriguez, I. *et al.*, 1999; Del Punta, K. *et al.*, 2002b). The distribution of these multiple glomeruli within each domain exhibits a high degree of variability compared to the convergence and position of glomeruli in the MOB, but there is a general similarity across animals.

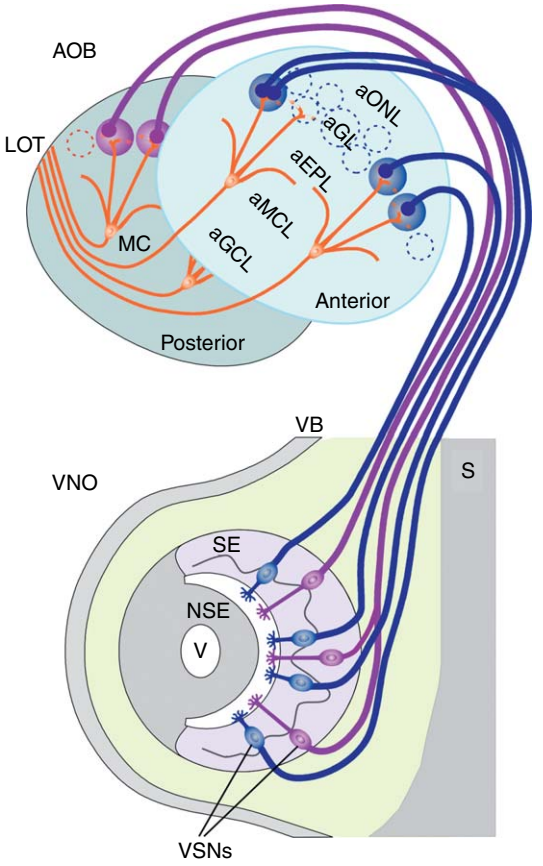

Figure 6 Diagram showing the mosaic projection of vomeronasal sensory neurons (VSNs). The sensory epithelium (SE) is segregated into two distinct zones, both of which express a unique set of transduction-related molecules: (1) an apical zone (blue VSNs) that expresses the G protein $G\alpha_{i2}$ as well as members of the V1R family of vomeronasal receptors, and (2) a basal zone that characteristically contains VSNs (purple) that express $G\alpha_o$ and members of the V2R receptor family. Unlike the main olfactory bulb, VSNs expressing the same receptors project to multiple glomeruli in the AOB, and AOB mitral cells (MC) innervate multiple glomeruli. The AOB can be further divided into mainly five layers depending on the cell types present, that is, the accessory olfactory nerve layer (aONL), accessory glomerular layer (aGL), the accessory external plexiform layer (aEPL), the accessory mitral cell layer (aMCL), and the accessory granule cell layer (aGCL). LOT, lateral olfactory tract; NSE, nonsensory epithelium; S, septum; V, blood vessel; VB, vomer bone.

4.43.4.2 Functional Organization of the Accessory Olfactory Bulb

With respect to circuit organization, the AOB appears quite similar to the MOB; however, there are points of significant differences in the arrangement of circuits in the AOB. Within each glomerulus, VSN axons synapse onto the dendrites of mitral, tufted, and juxtaglomerular neurons. Electrophysiological studies in tissue slices demonstrated that, similar to OSNs in the main olfactory system, glutamate is the primary VSN neurotransmitter (Dudley, C. A. and Moss, R. L., 1995; Jia, C. *et al.*, 1999). Glutamatergic transmission from the VSN to postsynaptic target neurons is heavily dependent on alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kainate receptors for fast postsynaptic responses, and on *N*-methyl-D-aspartate (NMDA) receptors for slower components of the response (Dudley, C. A. and Moss, R. L., 1995; Jia, C. *et al.*, 1999). AOB mitral cell responses in the awake animal consist of a gradual elevation in firing rate over 2–5 s following contact with a stimulus, for example, anogenital investigation (Luo, M. *et al.*, 2003). The slowly evolving elevation of firing rate is in sharp contrast to other sensory systems such as vision, auditory or somatosensory where the precise timing of stimulus-triggered responses are highly conserved. However, the slow evolution of activity in the AOB mitral cell is consistent with the nature of odor access and receptor kinetics discussed above. The relatively slow characteristics of olfactory responses could allow for significant temporal evolution of local inhibitory feedback and cortical feedback during the detection event, as postulated by Laurent and coworkers for the main olfactory system (for a review, see Laurent, G., 2002).

VSNs expressing the same receptor gene project to the AOB in a complex, multiglomerular pattern, but how is this complex glomerular projection pattern read by the AOB? The major output neuron of the AOB, the mitral cell, has a strikingly different structure to mitral cells of the MOB. It has been known for nearly a century that AOB mitral cells possess multiple apical dendrites, upto five, that each ramify within a different glomerulus (Cajal, R. S., 1911; Takami, S. and Graziadei, P. P., 1990; 1991) (Figure 7(a)). It was thought for many years that this multiglomerular organization of mitral cell dendrites allowed for sampling from different glomeruli and thus presumably different olfactory specificity; a cross-modality model. A logical prediction of this idea is that AOB mitral cells would be broadly tuned, capable of responding and integrating different kinds of vomeronasal input. A blend of pheromonal compounds could thus be integrated in the context of relative intensity of input by concurrent activation of glomeruli with different receptor identity. A difficulty with such a model is the requirement that mitral cell dendritic connectivity between different glomeruli precisely match

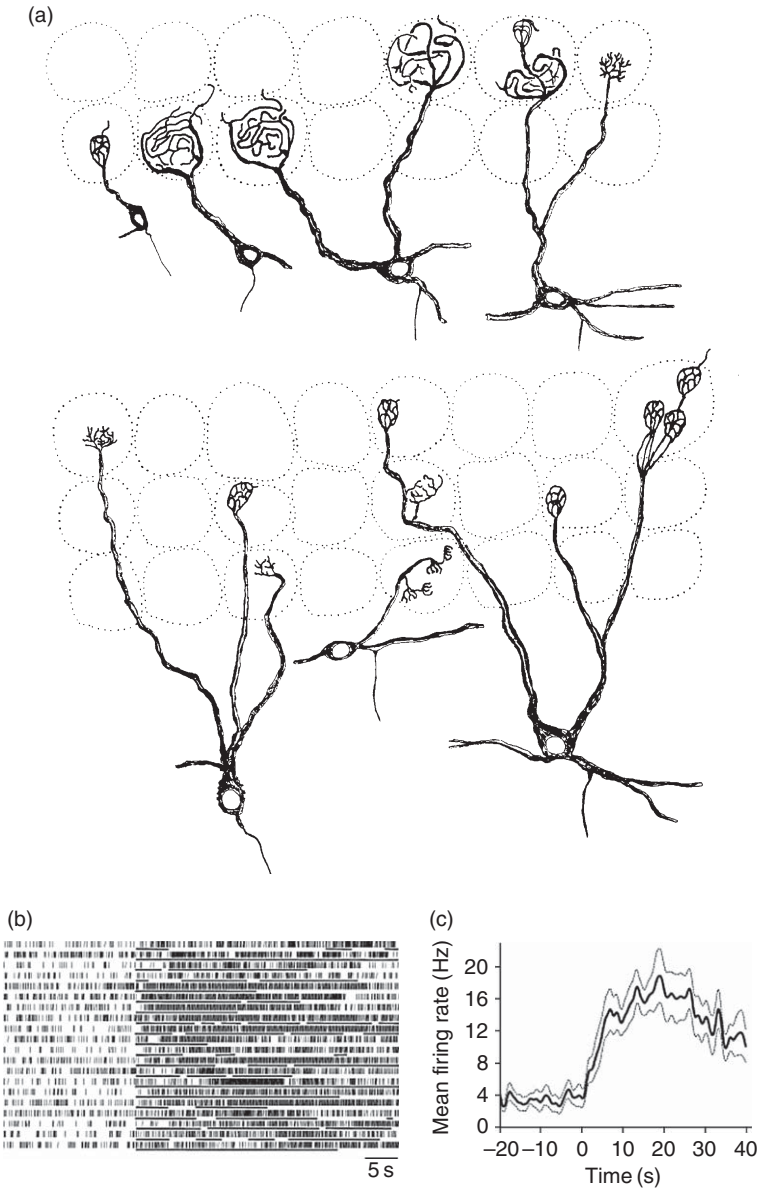

Figure 7 (a) Schematic drawing of accessory olfactory bulb (AOB) mitral and tufted cells. These cells have between one and five apical dendrites that terminate in different glomeruli. (b, c) Response kinetics of AOB neurons in the awake mouse. (b) Raster plots of the activation patterns of 14 AOB cells. Plots are aligned with the initiation of the first direct contact. Black bars beneath rasters represent periods of direct contact between the snout of test animals and the body of stimulus animals. (c) Plot of the mean firing rate (thick black line) from the AOB cells shown in (b). The thin gray lines represent ± 1 SEM. The activity of the AOB cells gradually increased following the initiation of active investigation, which is unlike the main olfactory bulb (MOB) neurons that respond invariably to odor ligands with rapid and abrupt changes in firing frequency. (a) Reprinted from Takami, S. and Graziadei, P. P.1991. Light microscopy Golgi study of mitral/tufted cells in the accessory olfactory bulb of the adult rat. J. Comp. Neurol. 311, 65–83, with permission from Wiley. (b, c) reprinted with permission from Luo, M., Fee, M. S., and Katz, L. C. 2003. Encoding pheromonal signals in the accessory olfactory bulb of behaving mice. Science 299, 1196–1201, AAAS.

biologically relevant pheromonal blends, a formidable problem of wiring specificity.

However, it was recently shown that the divergent pattern of VSN projections into the AOB could be rendered convergent due to the multiple glomerular projections of the mitral cell (Del Punta, K. *et al.*, 2002b). This study suggested that at least some of the mitral cell multiple processes, but not all, innervate glomeruli that receive axons from the same population of VSNs (Del Punta, K. *et al.*, 2002b).

The convergence of VSNs with the same receptor gene and presumably the same receptive field to a single mitral cell challenges the notion that AOB mitral cells would show a cross-modal response by integrating different sensory stimuli. Instead, AOB mitral cell response profiles may closely match those of the VSNs, modified by spatiotemporal circuit processing in the AOB; a labeled-line model. Because mouse VSNs, at least those of the apical layer, exhibit a narrow receptive field tuned to a single putative pheromone even at a wide range of concentrations (as discussed in the preceding section), a labeled line predicts that AOB mitral cells should thus exhibit similar narrow response profiles and that increasing concentrations of ligand will not recruit additional mitral cells. Elegant work by Luo M. and Katz L. C. (2004) in awake, behaving mice tested these predictions. Single unit recordings from the mitral cell layer of the awake, behaving mouse showed a high degree of selectivity for sex and strain of animal used as the stimulus (Luo, M. *et al.*, 2003; Luo, M. and Katz, L. C., 2004) (Figures 7(b) and 7(c)). The high selectivity of AOB mitral cell physiological responses supports the notion of a labeled line from VSN to AOB mitral cell.

What then is the benefit of a divergent VSN projection that is subsequently rendered, at least in part, convergent at the AOB mitral cell? One possibility is that the formation of multiple glomeruli of the same receptor type may be important for enhancing signal to noise via glomerular level lateral inhibition. Multiple small glomeruli of the same type are adjacent to a greater number of other receptor type glomeruli compared to a single large glomerulus such as present in the MOB. In the MOB an extensive lateral interglomerular network allows for integration between numerous different receptor type glomeruli (Aungst, J. L. *et al.*, 2003); however, there does not appear to be such a long-range interglomerular network in the AOB (unpublished observations). The ensemble of multiple glomeruli of the same receptor type with only short interglomerular neuronal connections would still have the potential for extensive and diverse lateral inhibition compared to a single glomerulus of larger size. Luo M. and Katz L. C. (2004) observed inhibition that does not require preceding excitation, suggesting the presence of selective lateral inhibition. The authors attribute this to selective lateral inhibition at the level of granule–mitral–granule cell connections (discussed below), but the observation is also consistent with glomerular lateral inhibition.

Together, the recent studies on VNO and AOB support the notion that VNO–AOB follows a labeled line neural encoding strategy rather than a cross modality, and that AOB mitral cells could act as functional modules. Further evidence for the role of AOB mitral cells as functional units comes from recent cellular physiology experiments (Lowe, G., 2003; Urban, N. N. and Castro, J. B., 2005). Calcium imaging and paired dendritic recordings were used to show action potentials in AOB mitral cells back propagate without attenuation through the entire dendritic tree (Ma, J. and Lowe, G., 2004). This active nondecremental back propagation could assist in coordinating activity of all the mitral cells projecting to the same glomerulus. In the MOB mitral cells projecting to the same glomerulus show synchronous membrane oscillations that are likely to depend on intraglomerular coupling between the cells (Carlson, G. C., *et al.*, 2000; Schoppa, N. E. and Westbrook, G. L., 2001; 2002). If a similar coupling exists in the AOB the nonattenuating back propagation of action potentials would contribute to binding all the mitral cells of that glomerulus into a single responsive unit.

4.43.4.2.1 Interneurons

The AOB contains a sparse population of juxtaglomerular cells located between glomeruli, although relatively little is known about these cells. Golgi studies show the dendrites of these AOB juxtaglomerular cells ramify in the aGL (Cajal, R. S., 1911) and can be categorized into periglomerular (PG) neurons and tufted cells. Immunohistochemistry shows the presence of larger glutamate containing cells, presumably the tufted cells, and smaller γ-aminobutyric acid (GABA)-containing cells, presumably the inhibitory PG neurons (Takami, S. *et al.*, 1992a; Quaglino, E. *et al.*, 1999). The role of these interneurons is presumed to be similar to the MOB, although no studies have yet examined these cells in detail. Any role of these cells is, however, likely to be local to one or neighboring glomeruli as there is no indication of the extensive interglomerular network present in the MOB (unpublished observations).

AOB granule cells are a numerous population of GABAergic inhibitory neurons located in the deep layers of the AOB. Unlike the MOB the mitral and granule cell layers are less distinct in the AOB, with mitral and granule cells intermingled through the broad mitral cell layer, and dispersed granule cells present throughout the deeper granule cell layer. In general, MOB olfactory bulb granule cells are thought to play

two roles in the olfactory circuit; feedback inhibition of mitral cells and lateral inhibition between mitral cells. AOB mitral cells have lateral dendrites that run for hundreds of microns, significantly shorter than the multimillimeter lengths of MOB mitral cell lateral dendrites (Cajal, R. S., 1911; Takami, S. and Graziadei, P. P., 1990; 1991). However, as the AOB is smaller than the MOB the fraction of AOB within reach of the mitral lateral dendrites is very high. AOB granule cell dendrodendritic connections with mitral cells can be formed with the lateral dendrites or with the basal portions of the apical dendrites which, given the considerable distances that these lateral/apical dendrites can project, still allows for either feedback or lateral inhibition between diverse AOB mitral cells. Shepherd and co-workers using field potential and whole-cell recordings in AOB slices showed activation of the VN results in a sequence of neural responses in the AOB that is consistent with VN stimulation of mitral cells, followed by mitral cell dendrodendritic excitation of granule cells and subsequent reciprocal inhibition of mitral cells by granule cell GABA release (Jia, C. *et al.*, 1999). This work demonstrated the basic reciprocal mitral–granule–mitral inhibition circuit follows the same principles as the MOB. Mitral–granule–mitral lateral inhibition is also present in the AOB. Mitral cell inhibitory responses can occur without a preceding excitatory response in that cell, consistent with lateral inhibition from a distant excited mitral cell (Luo, M. *et al.*, 2003).

There have been numerous studies examining the patterns of neural activation using increased expression of c-fos (an immediate early gene) as an activity marker following stimulation with different strain/sex mouse urine/odor (for review Halpern, M. and Martinez-Marcos, A., 2003 and reference therein). These stimuli evoke c-fos activity in cells across all layers of the bulb, particularly in the granule and mitral layers. The dispersed location of mitral cells together with the inherent difficulties of attributing c-fos staining in nuclei to a particular cell type, make the mapping of AOB mitral cell activity problematic. However, these studies clearly show extensive c-fos activity in the granule cell layer which is consistent with the notion that there is extensive feedback and lateral inhibition shaping AOB output.

4.43.4.2.2 Subdivisions

The anterior and posterior domains of the AOB receive input from different populations of VSNs that express different families of receptor genes; thus, it is seems likely that different stimuli may elicit responses from only one of the two AOB domains. Although c-fos responses to natural stimuli are generally dispersed throughout the AOB there are reports of preferential activity to a species/sex difference in the rostral domain (Matsuoka, M. *et al.*, 1999). Optical imaging and field potential recordings of AOB slices showed electrical stimulation of the anterior aONL elicited activity from the anterior internal plexiform layer. Stimulation of parts of the posterior aONL suggest this region is further subdivided into a rostral two-thirds and caudal one-third AOB domain (Sugai, T. *et al.*, 2000). Additional evidence for these further divisions comes from recent genetic tract tracing showing a VSN–VR population projecting into a restricted middle part of the bulb, putatively into the more rostral part of the posterior division (Mombaerts, unpublished observation).

4.43.4.3 Outputs of the Accesory Olfactory Bulb

Track tracing studies from the 1960s and 1970s demonstrated that the central connections of the AOB and MOB to higher order olfactory structures are essentially nonoverlapping. These observations lead to the hypothesis that the AOB and MOB pathways would serve different functional roles (Winans, S. S. and Scalia, F., 1970; Raisman, G., 1972; Scalia, F. and Winans, S. S., 1975). Subsequent research over the past 30 years has clarified many behavioral roles that are specific to vomeronasal function (several example effects are discussed in Section 4.43.5). The AOB has direct projections (Figure 8) to the medial (Me) and posteromedial cortical amygdaloid nucleus (PMCo), the BST, and the BAOT (Scalia, F. and Winans, S. S., 1975; de Olmos, J. *et al.*, 1978; Shipley, M. T. and Adamek, G. D., 1984). Together these structures can be called the accessory olfactory cortex (AOC). A recent examination of higher cortical projections from the anterior and posterior domains of the mouse AOB concluded both domains project into the same brain regions (Sugai, T. *et al.*, 2000). However, mitral cells in the opossum anterior AOB appear to project into deep cell layers of the medial amygdaloid complex (corresponding to the ventral division of the medial amygdala in rats) while the posterior AOB domain mitral cells project only into the superficial layers (Martinez-Marcos, A. and Halpern, M., 1999). Opossum mitral cell projections from the different domains of the AOB to the other AOC structures were essentially overlapping (Martinez-Marcos, A. and Halpern, M., 1999). These data show the

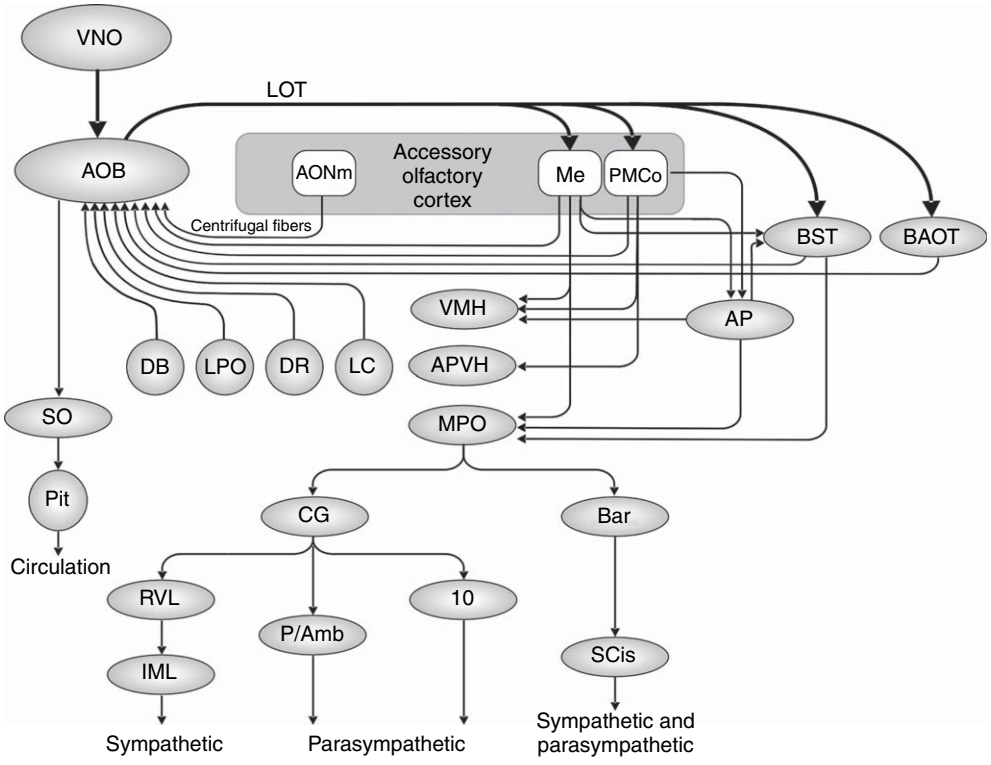

Figure 8 Diagrammatic representation of the connections of the accessory olfactory bulb (AOB) with cortical and subcortical structures. The major outputs of the AOB along the lateral olfactory tract (LOT) are shown at the upper part of the diagram. The major centrifugal inputs from the cortical regions back to the olfactory bulb are shown centrally along with higher-order connections. Emphasis is placed on possible circuits that mediate output responses such as autonomic, behavioral, or hormonal changes. 10, dorsal motor nucleus of the vagus; AOB, accessory olfactory bulb; AONm, anterior olfactory nucleus, medial division; AP, posterior amygdaloid nucleus; APVH, anterior periventricular hypothalamus; BAOT, bed nucleus of the lateral olfactory tract; Bar, Barrington's nucleus; BST, bed nucleus of the stria terminalis; CG, central (periaqueductal) gray; DB, nucleus of the diagonal band; DR, dorsal raphe nucleus; LC, locus coeruleus; LPO, lateral preoptic area; Me, medial amygdaloid nucleus; MPO, medial preoptic area; P/Amb, nucleus ambiguous and periambigual area; PMCo, posteromedial cortical amygdaloid nucleus; Pit, pituitary; RVL, rostroventrolateral medulla; SCis, lumbosacral spinal cord; SO, supraoptic nucleus; VMH, ventromedial hypothalamic nucleus; VNO, vomeronasal organ.

divergence into segregated pathways in the AOB generally, with some species differences, converge to the same higher brain regions.

The structures comprising the AOC are complex in organization and innervate many cortical and subcortical structures throughout the central nervous system (CNS). For example, the medial amygdala is a complex heterogeneous structure that is partitioned into at least four regions on the basis of cytoarchitecture, neurotransmitter content, hormone receptor expression, connections and putative functions (for a review, see Paxinos, G., 2004). The amygdala is a neural structure thought to be heavily involved in emotive states including behaviors such as mating and aggression behaviors in rat. The Me and PMCo have projections to other amygdaloid nuclei, notably the posterior amygdaloid nucleus (AP) (Canteras, N. S. *et al.*, 1992), and to the medial preoptic area and the hypothalamus (for a review, see Shiosaka, S. *et al.*, 1982). The AP appears to receive convergent input from both the Me and PMCo and projects heavily upon some of the same structures targeted by Me and PMCo, namely the medial preoptic area and the ventromedial hypothalamic nucleus. Some of these secondary olfactory connections strongly influence sexual drive. The posterodorsal part of Me (MePD) contains neurons that project to four cell groups that are known to be sexually dimorphic and differ in their roles in reproduction. The medial preoptic area (MPO) is one of the sexually dimorphic targets of MePD and lesions of MPO decreases male copulatory behavior (for review Simerly, R. B. *et al.*, 1989). These higher-order connections of the AOB are highly consistent with roles for VNO function in

mating, species recognition, and aggression. Indeed, studies of c-fos expression following mating in the AOB and higher brain regions by many investigators clearly establishes a link for vomeronasal activity in this behavior (Brennan, P. A. *et al.*, 1992; Fernandez-Fewell, G. D. and Meredith, M., 1994; Halem, H. A. *et al.*, 1999; Fewell, G. D. and Meredith, M., 2002).

4.43.4.4 Centrifugal Afferents to the Accessory Olfactory Bulb

The AOB receives heavy centrifugal inputs from higher brain regions (Figure 8), although from fewer sites than the MOB. The major olfactory cortex afferents to AOB are from the BST, the nucleus of the accessory olfactory tract, the Me, and the PMCo (de Olmos, J. *et al.*, 1978; Shipley, M. T. and Adamek, G. D., 1984). A restricted part of the medial division of AON sends a dense projection to the granule cell layer of AOB (Rizvi, T. A. *et al.*, 1992), but all other divisions of AON lack connections with AOB. Several of these structures (e.g., the amygdala) receive input from the AOB and thus are situated to provide a potential rapid feedback circuit with the AOB.

There are also extensive nonolfactory modulatory inputs to the AOB arising from the nucleus of the diagonal band (DB), lateral preoptic area, median and dorsal raphe, and the locus coeruleus (LC). The terminal distribution of these common inputs differs in AOB and MOB, especially with respect to the cholinergic inputs from the DB and serotonergic inputs from the LC. The cholinergic–serotonergic inputs to AOB are mainly to the granule cell layer and internal plexiform layer and only sparsely to the glomerular layer, whereas in the MOB glomeruli are heavily innervated (McLean, J. H. and Shipley, M. T., 1987; Le Jeune, H. and Jourdan, F., 1991). These fibers are thought to target PG cells in the MOB (McLean, J. H. and Shipley, M. T., 1987), as the AOB has fewer PG cells this may account for the paucity of serotonin and acetylcholine innervation of the AOB glomerular layer. The roles of these extensive centrifugal fiber tracts in circuit processing in the AOB (and the MOB) are largely unknown.

4.43.5 Mechanisms of Behavior

Following the pioneering work of Powers J. B. and Winans S. S. (1975), a vast number of studies have been published on the role of the VNO and AOS in behavioral responses using a variety of animal models such as hamsters, voles, mice, rats, farm animals, and reptiles. This work has been summarized previously and the reader is referred to several extensive reviews (Meredith, M., 1983; Wysocki, C. J. and Meredith, M., 1987; Halpern, M., 1987; Johnston, R. E., 2000; Halpern, M. and Martinez-Marcos, A., 2003). Here, we will focus on only a few selected functions of the AOS for which the evidence seems particularly well established. Most recently, it has become clear that the mammalian main and AOSs detect, at least in part, overlapping sets of sensory stimuli (see Spehr, M. *et al.*, 2006) and that both systems play important roles in the regulation of social behaviors and the sensing of pheromone-like chemical signals. Consequently, it has been suggested that the main olfactory and vomeronasal systems should be viewed as complementary rather than separate pathways for chemical communication (Brennan, P. A. and Keverne, E. B., 2004; Shepherd, G. M., 2006). Current work is focusing on a dissection of the different nasal subsystems in behavioral responses using a combination of gene-targeting methods and more classical lesioning approaches. However, this goal is proving more difficult than previously thought because of the growing complexity of the function of the mammalian nose in chemosensory communication and the fact that each method exhibits specific limitations. For example, surgical removal of the VNO (VNX) also leads to removal of the terminal nerve system (Wysocki, C. J. and Meredith, M., 1987; Wysocki, C. J. and Lepri, J. J., 1991) and lesioning of the MOE by application of zinc sulphate is often incomplete. Similarly, the use of gene-targeted animals can involve a number of limitations. For example, deletion of the ion channel TRPC2 causes a dramatic loss in VSN sensitivity rather than a total loss of function (Leypold, B. G. *et al.*, 2002) and deletion of the CNGA2 subunit as a method to disrupt signaling in the main olfactory epithelium is likely to cause other deficits in the CNS (Mandiyan, V S. *et al.*, 2005). Furthermore, the role of these signal transduction molecules in additional olfactory subsystems (Figure 2(a)) such as the guanylyl cyclase type (GC-D) cell system (Zufall, F. and Munger, S. D., 2001), the septal organ of Masera (Tian, H. and Ma, M., 2004), and the Grueneberg ganglion (Fuss, S. H. *et al.*, 2005; Storan, M. J. and Key, B., 2006) is not yet clear. Thus, we must be careful in the interpretation of behavioral results based on the use of either method and in most cases, only a combination of methodological approaches, together with parallel analysis at the cellular level, will provide definitive answers. Table 3 shows a comparison of behavioral impairments caused by surgical VNO ablation or genetic manipulation of VSNs.

Table 3 Behavioral impairments, relative to wild type, caused by surgical ablation of VNO or genetic manipulation of VSNs

Phenotype	*VNO ablation*[a]	*Trp2*$^{-/-}$[b,c]	*V1Rab*$^{-/-}$[d]	*β2m*$^{-/-}$[e]	$G\alpha_{i2}^{-/-}$[f]
Male sexual behavior directed to females	Reduced, fewer mounts and longer latency, experience-dependent	Normal	Reduced drive to initiate sexual behavior	Not reported	Normal
Male sexual behavior directed to males	Not reported	Increased	Normal/reduced	Normal	Normal
Male ultrasonic vocalizations to females	Eliminated/reduced, experience-dependent	Normal	Normal	Not reported	Not reported
Male ultrasonic vocalizations to males	Eliminated/reduced, experience-dependent	Increased	Not reported	Not reported	Not reported
Male aggression to intruder male	Eliminated	Eliminated	Normal	Eliminated	Reduced, depends on genetic background
Maternal aggression to intruder male	Eliminated	Eliminated	Eliminated	Not reported	Eliminated/reduced

4.43.5.1 Detection of Heterospecific Signals

Work in the AOS of snakes has provided the best example that the VNO can be involved in the initiation of behavioral responses to both social and nonsocial chemical cues. The role of the snake VNO in prey recognition and response to prey odors has been especially well documented (Halpern, M., 1987; Halpern, M. and Martinez-Marcos, A., 2003; Baxi, K. N. *et al.*, 2006). Snakes with lesioned VNs stop following prey odor trails and eventually stop eating prey (Halpern, M., 1987). As pointed out by Baxi K. N. *et al.* (2006), heterospecific stimuli such as those involved in foraging cannot be considered pheromones.

4.43.5.2 Male Aggression to Intruder Males

In rodents, one of the best examples for a role of the VNO in the regulation of social behaviors comes from work on intermale aggression in mice using a resident–intruder assay. In this assay, a male intruder is added to the home cage of a singly housed test mouse. After initial olfactory exploration, a wild-type resident mouse will initiate vigorous attacks against the intruder. The involvement of the VNO in this type of aggression is clearly demonstrated by several studies using surgical VNO ablations (Clancy, A. N. *et al.*, 1984; Wysocki, C. J. and Lepri, J. J., 1991; Halpern, M. and Martinez-Marcos, A., 2003). An excellent correspondence (Table 3) exists between these studies and more recent work that employed mice with a targeted mutation in the cation channel gene TRPC2, also showing absence or strong reduction of male–male aggression (Leypold, B. G. *et al.*, 2002; Stowers, L. *et al.*, 2002). Consistent with these findings, TRPC2-deficient mice fail to establish territorial dominance relationships (Leypold, B. G. *et al.*, 2002). Together, these results demonstrate the importance of the VNO in sensing male chemosignals and initiating an appropriate aggressive response.

4.43.5.3 Maternal Aggression to Intruder Males

The correspondence between the behavioral effects of the TRPC2 deletion and surgical VNO ablation is also very good in the context of maternal aggression (Table 3). Female mice are usually not aggressive toward intruders, but lactating females vigorously attack intruder males (Gandelman, R. *et al.*, 1972). Ablation of the VNO eliminates the display of maternal aggression (Bean, N. J. and Wysocki, C. J., 1989; Wysocki, C. J. and Lepri, J. J., 1991) and this aggression is also absent in TRPC2$^{-/-}$ females (Leypold, B. G. *et al.*, 2002). Similarly, maternal aggression is substantially reduced in mice lacking a cluster V1R receptor genes (V1rab$^{-/-}$, Del Punta, K. *et al.*, 2002a) as well as in Gα_{i2} mutant mice (Norlin, E. M. *et al.*, 2003). Thus, it seems clear that the loss of specific sensory inputs in the VNO causes a loss of the display of maternal aggression in mice. Interestingly, although the V1rab$^{-/-}$ mice fail to initiate maternal aggression, there are no differences in male–male aggression compared with control mice (Del Punta, K. *et al.*, 2002a). This suggests that different male chemosignals might be responsible for triggering aggression in males and females (Brennan, P. A. and Keverne, E. B., 2004).

4.43.5.4 Male Mating Behavior

Although there is abundant evidence for an involvement of the rodent VNO in male sexual behavior (Wysocki, C. J. and Meredith, M., 1987; Halpern, M. and Martinez-Marcos, A., 2003) its exact role remains unclear, possibly due to complex interactions with other chemosensory systems, especially the main olfactory system (Brennan, P. A. and Keverne, E. B., 2004). Initial studies were done in hamster where approximately one-third of male hamsters with VN cuts developed a severe mating deficit (Powers, J. B. and Winans, S. S., 1975). Subsequently, Meredith M. (1986) showed that sexually inexperienced male hamsters are severely defective in male–female mating behavior when the VNO is removed, but that prior sexual experience can mitigate the lesion effects. Results in mice are less clear. Although several studies reported the importance of an intact VNO for the normal display of sexual behavior in male mice (Clancy, A. N. *et al.*, 1984; Bean, N. J. and Wysocki, C. J., 1989; Wysocki, C. J. and Lepri, J. J., 1991), a more recent study found that the rates of mounting and intromission and the timing of ejaculation are equivalent in sexually naive control and VNX mice (Pankevich, D. E. *et al.*, 2004).

In TRPC2$^{-/-}$ mice, sexual behavior toward females appears to be unaffected. Instead, TRPC2$^{-/-}$ males show abnormally high levels of mounting behavior toward other males (Leypold, B. G. *et al.*, 2002; Stowers, L. *et al.*, 2002), a phenotype not previously observed in surgical lesioning studies (Pankevich, D. E. *et al.*, 2004). It has been argued that the VNO plays an essential role in gender discrimination (Stowers, L. *et al.*, 2002), but this is currently debated (Pankevich, D. E. *et al.*, 2004).

4.43.5.5 Male Ultrasonic Vocalizations

Male mice emit 70 kHz precopulatory vocalizations in the presence of female mice or their chemical cues (Nyby, J. *et al.*, 1979; Wysocki, C. J. and Lepri, J. J., 1991). Deafferentation of the VNO abolishes vocalizing in sexually naïve males and reduces it in males that have had previous sexual experience (Wysocki, C. J. and Lepri, J. J., 1991). However, ultrasonic vocalizations persist in TRPC2$^{-/-}$ males and are not suppressed in the presence of male chemosignals (Stowers, L. *et al.*, 2002; Brennan, P. A. and Keverne, E. B., 2004). The discrepancies between the effects of surgical and genetic lesions might be explained, in part, by the result that the loss of TRPC2 does not cause a complete loss of function in the VNO (Leypold, B. G. *et al.*, 2002).

4.43.5.6 Timing of Puberty, Cyclicity, and Ovulation in Females

A vast literature exists on the role of the VNO in altering the course of puberty and modulating female cyclicity and ovulation in a variety of species (Meredith, M. *et al.*, 1983; Halpern, M., 1987; Halpern, M. and Martinez-Marcos, A., 2003). Among these effects, puberty acceleration (Vandenbergh, J. G., 1983), caused by exposure to male chemosignals during female development, represents one of the best examples for a clear dependence on an intact VNO (Kaneko, N. *et al.*, 1980; Lomas, D. E. and Keverne, E. B., 1982; Sanchez-Criado, J. E., 1982). Novotny and collaborators have identified several volatile urine constituents that are capable of accelerating puberty in female mice (Novotny, M. V. *et al.*, 1999a; 1999b). Other evidence suggests that the delay of the onset of puberty, observed in crowded female house mice, depends also upon

a functional VNO (Wysocki, C. J. and Lepri, J. J., 1991). Further work using animals with specific genetic deletions will be required to examine some of these effects.

4.43.5.7 Hormonal Responses

Some of the VNO-dependent functions summarized above depend on the coordination of neuroendocrine functions and the release of specific hormones. Significant efforts have been undertaken to establish a direct link between VNO stimulation and hormonal function (Keverne, E. B., 1983; Meredith, M. *et al.*, 1983). It is important to note that the level of reproductive hormones can also be influenced by the detection of chemosignals via the main olfactory system (Meredith, M., 1998) and current work is focusing on establishing neural connections between chemosensory neurons of the main and AOSs and neural circuits involved in hormone regulation (Boehm, U. *et al.*, 2005; Yoon, H. *et al.*, 2005; Shepherd, G. M., 2006). With respect to VNO stimulation, some of the best evidence comes from measurement of the gonadotropin luteinizing hormone (LH), which itself depends on the release of gonadotropin releasing hormone (GnRH, also known as luteinizing hormone releasing hormone (LHRH)) (Wysocki, C. J. and Meredith, M., 1987; Meredith, M., 1998; Halpern, M. and Martinez-Marcos, A., 2003). Female rats, when exposed to males or their odors, show a surge in LH and this effect is absent after removal of the VNO or lesioning of the AOB (Beltramino, C. and Taleisnik, S., 1983). Electrical stimulation of the AOB or medial (vomeronasal) amygdala produces a similar LH surge, whereas stimulation of the MOB or lateral (olfactory) amygdala does not elicit a facilitatory but rather an inhibitory effect (Beltramino, C. and Taleisnik, S., 1978; 1979).

Male mice exhibit a plasma testosterone surge after an encounter with strange females or their odors (Macrides, F. *et al.*, 1975). Removal of the VNO blocks this testosterone surge after exposure to an anesthetized female (Wysocki, C. J. *et al.*, 1983). Similarly, reflexive release of LH following exposure to female urine odor is blocked in VNO-lesioned male mice, although exposure to females did cause LH responses in these mice (Coquelin, A. *et al.*, 1984). These results stress the existence of multiple convergent pathways involved in LH regulation.

4.43.5.8 Pregnancy Block and Individual Recognition in Females: The Bruce Effect

One of the best-known examples of olfactory imprinting in adult vertebrates is the selective pregnancy block (or Bruce effect; Bruce, H. M., 1959) in the mouse, which depends on the formation and maintenance of a long-lasting odor recognition memory by the vomeronasal system (Brennan, P. *et al.*, 1990; Brennan, P. A. and Keverne, E. B., 1997; Halpern, M. and Martinez-Marcos, A., 2003). The Bruce effect occurs when a recently mated female mouse aborts if exposed to the urine odor of a male genetically different from the stud male (Figure 9). This unfamiliar male odor results in pregnancy block and return to estrus in the recently mated female. Keverne and colleagues suggest that the dendrodendritic synapse between granule cells and mitral cells in AOB may be critical for odor memory of the mate in the female (Keverne, E. B. and de la Riva, C., 1982; Rosser, A. E. and Keverne, E. B., 1985; Kaba, H. *et al.*, 1989). The Bruce effect can be abolished if noradrenergic centrifugal input to the female AOB is blocked immediately after mating, presumably before olfactory memories of the mate are formed (Keverne, E. B. and de la Riva, C., 1982; Rosser, A. E. and Keverne, E. B., 1985). Thus, noradrenalin appears to be important in strengthening the memory of the odor of the mating partner. Noradrenergic innervation of the AOB derives from LC projections primarily to the accessory granule layer (aGCL) and accessory mitral cell layer (aMCL) with lower density in the accessory external plexiform layer (aEPL) and aGL (McLean, J. H. *et al.*, 1989). Based on these light microscopic studies it was suggested that the major target of the noradrenalin input are granule cells (McLean, J. H. *et al.*, 1989). Thus, noradrenalin exciting granule cells and enhancing inhibition of a subset of mitral cells for several hours following mating may facilitate this selective odor memory.

The MHC peptide ligands are the first identified vomeronasal stimuli that can mediate the Bruce effect. To show that MHC peptides provide a crucial signal among the plethora of other cues present in male urine, peptides characteristic of a disparate MHC molecule were synthesized and added to the urine of a familiar male. Compared to the addition of cognate peptides, which had no effect, disparate peptides caused pregnancy block by otherwise familiar urine (Leinders-Zufall, T. *et al.*, 2004) (Figure 9). These results indicate that MHC peptides are recognized as natural odors and convey genotypic information in the context of a distinct social behavior (Boehm, T. and Zufall, F., 2006).

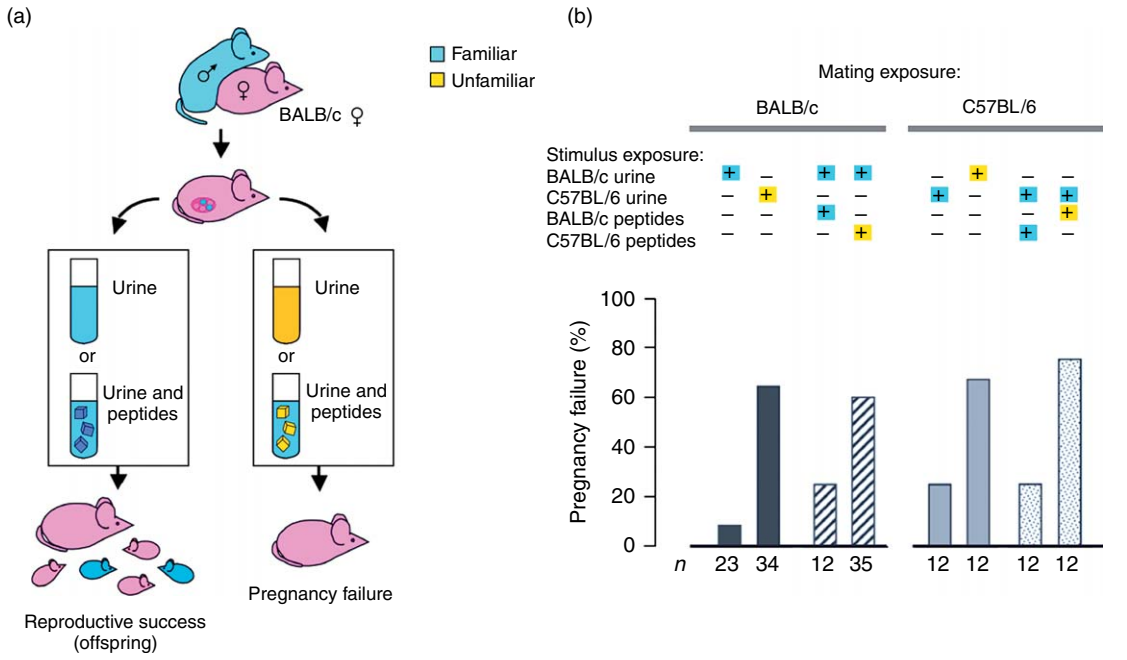

Figure 9 (a) Processing of major histocompatibility complex (MHC) peptide ligands via the accessory system provides a crucial signal in the pregnancy block paradigm of female mice (the Bruce effect), where disparate but not cognate peptides caused pregnancy block when added to otherwise familiar urine. (b) Percent pregnancy failure in female BALB/c (H-2d haplotype) mice mated with either BALB/c (H-2d haplotype) or C57BL/6 (H-2b haplotype) males. Exposure to different male urine types, which, in some cases, were supplemented with MHC class I peptides specific for BALB/c or C57BL/6 haplotypes is indicated. Reprinted with permission from Leinders-Zufall, T., Brennan, P., Widmayer, P., Chandramani, S. P., Maul-Pavicic, A., Jager, M., Li, X. H., Breer, H., Zufall, F., and Boehm, T. 2004. MHC class I peptides as chemosensory signals in the vomeronasal organ. Science 306, 1033–1037, AAAS.

In summary, it is now clear that the AOS is involved in a wide variety of functions including complex mechanisms such as those mediating the sensing of genome composition of a conspecific. The upcoming years, undoubtedly, will provide further exciting results with respect to the role of the VNO and AOS in chemical communication.

Glossary

vomeronasal organ (VNO) Sensory olfactory structure, physically separate from the main olfactory system and present in mammals, amphibians, and reptiles. Its function is often linked to pheromone perception.

V1r receptors Pheromone receptors expressed by vomeronasal sensory neurons present in the apical part of the vomeronasal sensory neuroepithelium in rodents.

V2r receptors Putative pheromone receptors expressed by vomeronasal sensory neurons present in the basal part of the vomeronasal sensory neuroepithelium in rodents.

4.44.1 Introduction

The survival of multicellular organisms depends on their ability to perceive and recognize the outside and their own inside worlds. The main tool selected by evolution to achieve these basic tasks is based on the expression of multiple and different receptors, in specific cells. These cells then either directly respond to the stimuli, or instead transmit the information to others, which process the signals. To achieve this general need for receptor variability, various strategies have been selected by different systems and species. The vertebrate immune system, for example, bases its T-cell receptor (TCR) and Ig remarkable diversity on genomic recombination between a relatively limited number of coding segments. Another inventive strategy, used by many life forms including viruses, achieves variability by random mutation of messenger RNA transcripts. A very different option, which is based neither on genome recombination nor on transcript alteration, is used by vertebrate chemosensory systems to face the outside world: they benefit from receptor gene repertoires of amazing size and diversity already present in the genomes, which directly translate into an exceptional variability of chemoreceptors. Thus, odorant, taste, and vomeronasal receptor genes represent a substantial part of the coding fraction of mammalian genomes.

Vomeronasal receptor genes will be discussed here. Although some of their characteristics may be shared by odorant and taste receptor genes, they should not be assumed to be so, since their likely direct involvement in pheromone perception involved specific evolutionary pressures, pressures probably different from those which affected other chemosensory receptor genes. Moreover, the signal transduction cascades of sensory cells expressing odorant or vomeronasal receptors, but also their

targets in the brain, two processes which directly involve the expressed chemoreceptors, are dissimilar.

In mammals, pheromones are mostly (but not only) perceived by the vomeronasal organ. Two large putative seven transmembrane receptor families, the V1r and V2r superfamilies (Dulac, C. and Axel, R., 1995; Herrada, G. and Dulac, C., 1997; Matsunami, H. and Buck, L. B., 1997; Ryba, N. J. and Tirindelli, R., 1997), are almost exclusively expressed by vomeronasal sensory neurons.

4.44.2 V1r Receptors

4.44.2.1 On the Size of the Repertoires

All mammalian genomes apparently contain V1r genes. V1r repertoire sizes can be relatively limited, such as in dogs, for example, with only 8–10 potentially functional V1r genes (Rodriguez, I., 2005; Young, J. M., 2005), or particularly expanded such as in mice, where V1rs number about 160 (Rodriguez, I. *et al.*, 2002; Zhang, X. *et al.*, 2004) (Figure 1). Other species, such as cows or opossums, possess V1r repertoires of intermediate size (Grus, W. *et al.*, 2005). A few potentially functional V1r genes (among many pseudogenes; Giorgi, D. *et al.*, 2000; Kouros-Mehr, H. *et al.*, 2001) have been reported in primates, including humans (Rodriguez, I. *et al.*, 2000; Rodriguez, I. and Mombaerts, P., 2002). This may appear surprising since catarrhine primates only possess a vestigial and thus likely nonfunctional vomeronasal organ after birth (Maier, W., 1997) (a situation thought to be a result of trichromatic vision acquisition; Liman, E. R. and Innan, H., 2003; Zhang, J. and Webb, D. M., 2003; Gilad, Y. *et al.*, 2004). Possibly explaining the presence of V1r genes without functional vomeronasal system, expression of V1r genes has been reported outside the vomeronasal organ, in the main olfactory epithelium, in some species (Rodriguez, I. *et al.*, 2000; Wakabayashi, Y. *et al.*, 2002; Karunadasa, D. K. *et al.*, 2006). Thus, despite our strong taste for clear-cut expression profiles, the exclusive association between V1r expression and vomeronasal function is incorrect. This parallels the wrongly assumed functional dichotomy between the main olfactory and the vomeronasal systems, supposedly exclusively responsible for odor and pheromone perception, respectively. The origin of V1rs dates back apparently over 450 million years ago, since V1rs have also been identified in teleost species (Pfister, P. and Rodriguez, I., 2005). In these species, however, and unlike all mammals that express numerous V1rs, a very limited number of V1r genes are present in the genome (Pfister, P. *et al.*, 2007; Shi, P. and Zhang, J., 2007). These observations argue both for the presence of V1rs in other vertebrate phyla such as reptiles, and for a specific advantage in non-teleost species to maintain large and diversified V1r repertoires.

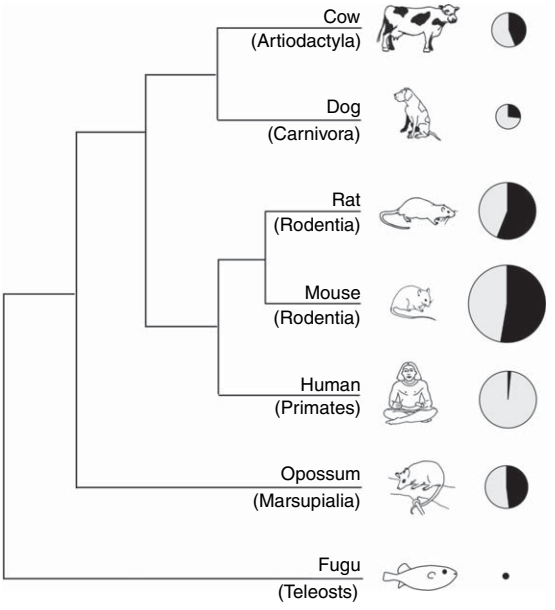

Figure 1 Variability of the V1r repertoire size between different vertebrate species. Pies represent the complete V1r repertoires corresponding to each species, and their surface the number of V1r genes. Black and gray indicate potentially functional V1r genes and pseudogenes, respectively. Adapted from Rodriguez, I. 2005. Remarkable diversity of mammalian pheromone receptor repertoires. Proc. Natl. Acad. Sci. U.S.A. 102, 6639–6640.

In addition to functional genes, a sizeable number of V1r pseudogenes are found in most species. Functional V1r genes are indeed sometimes less numerous than pseudogenic sequences, even in orders with well-developed vomeronasal systems such as rodents (Giorgi, D. and Rouquier, S., 2002; Rodriguez, I. *et al.*, 2002; Grus, W. E. and Zhang, J., 2004; Young, J. M. *et al.*, 2005) (Figure 1). Based on the sequence of their products, V1r genes can be divided into multiple, highly divergent families (12–15 in rodents), which only share a few common, highly conserved amino acids. Intrafamily homologies typically range from 40% to 98%, while interfamily identities can be as low as 15% (Rodriguez, I. *et al.*, 2002).

But does size matter? The very closely related and numerous V1r genes in a given family may each play a specific role and be responsible for the recognition of a narrow set of agonists; alternatively, these could represent a very redundant set of receptors with very little

evolutionary pressure to stay intact at the individual level, a view possibly supported by the large number of pseudogenes found in each family. Genetic experiments involving the partial deletion of defined V1r families, and the analysis of the potential resulting behavioral deficits have not yet settled this issue.

4.44.2.2 Remarkably Variable Repertoires

The recent sequencing of multiple mammalian genomes allowed the comparison of complete V1r repertoires between different species. These comparisons led to the surprising observation that V1r genes are not only highly variable inside the repertoire of a given species, but that repertoires of different species are also remarkably different (Lane, R. P. *et al.*, 2004). Thus, the parallel exploration of the cow, dog, opossum, and mouse V1r repertoires revealed species-specific expansions and absence of some V1r families (Grus, W. *et al.*, 2005). More unexpected, a similar observation was made when analyzing the mouse and rat V1r repertoires. Although both of these species are closely related and mostly express common V1r families, each also possesses their own V1r receptor families (Grus, W. E. and Zhang, J., 2004; Lane, R. P. *et al.*, 2004; Shi, P. *et al.*, 2005). V1r repertoires are thus characterized by rapid gene turnover and lineage-specific phylogenetic clustering, via gene duplications, deletions, and gene conversions.

A closer look at the evolutionary forces acting on these genes revealed that the diversification of the V1r repertoires, both inside a given species and between species, is at least partly the result of positive Darwinian selective pressure (i.e., the fixation of mutations that alter the translated sequence were favored over those which did not) (Mundy, N. I. and Cook, S., 2003; Lane, R. P. *et al.*, 2004; Shi, P. *et al.*, 2005). Positive selection has been observed in a few genes, evolving rapidly and often involved in the recognition of foreign molecules or cells, and usually related to the immune or fertilization processes. This latter function involves the recognition of same-species gametes, or the nonrecognition of gametes from different species: variability is there thought to provide postmating species barriers. One may suggest that V1r gene variability could similarly provide reproduction barriers, but in this case premating barriers, allowing only individuals possessing a given set of V1r receptors to adequately respond to the pheromonal blends of their own species. An attractive hypothesis would be to consider V1r diversity or novelty as potentially instrumental during speciation events, by their contribution to premating reproductive isolation. In favor of such possible role in speciation, V1r receptors are known to be narrowly tuned (Leinders-Zufall, T. *et al.*, 2000), unlike odorant receptors, and are therefore likely to dramatically alter perception and thus social behavior if lost or modified. In addition, in support of this view, a link between pheromone perception and speciation has been observed in a moth species (*Ostrinia*), in which changes in pheromone signaling and perception apparently allowed isolation and possibly speciation (Roelofs, W. L. *et al.*, 2002).

4.44.2.3 Clustered Gene Families

V1r families are often organized in clusters in the genome, and are present on virtually all autosomes in the few species where this was analyzed. These clusters result from multiple duplication events, possibly facilitated by Line1 repetitive elements, elements which are found at unusual high density in genomic regions harboring V1r genes (Lane, R. P. *et al.*, 2002; Lane, R. P. *et al.*, 2004), and whose retrotransposition apparently correlates with V1r duplications (Lane, R. P. *et al.*, 2004). Although V1rs are multiexonic genes (usually 2 or 3 exons), V1r coding sequences are entirely included in single exons (often the last one), similarly to many other G-coupled receptor genes. As previously mentioned, V1r families are organized, or better said found, in clusters; each of these contain multiple V1r units, whose transcription orientation is apparently random. Evidence for cluster-mediated regulatory mechanisms has recently been reported by us (Roppolo, D. *et al.*, 2007). Each V1r gene contains a relatively large segment of about 600 bp, located mostly upstream its transcription start site and overlapping slightly with the 5′-untranslated region, which is remarkably conserved (over 80%) between members of a given V1r family but not between different V1r family members (Lane, R. P. *et al.*, 2002; Lane, R. P. *et al.*, 2004). This observation contrasts with the poor promoter sequence conservation reported for odorant receptor genes. The role of these ultraconserved elements, largely more conserved than what one would expect from conventional promoters, is unknown.

4.44.2.4 Monogenic and Monoallelic V1r Expression

At the base of our current understanding of pheromone coding is the belief that each vomeronasal sensory neuron expresses a single (or a few) V1r receptor

genes (Dulac, C. and Axel, R., 1995), from a single, randomly chosen allele (Rodriguez, I. *et al.*, 1999). The perception of blends would thus involve a more central integration of multiple highly specific signals. Although monoallelic expression is experimentally well supported, the monogenic assumption still needs stronger experimental evidence. What is clear is that neurons expressing V1rs are not the same as those expressing V2rs. The first ones are expressed by sensory neurons located in the apical part of the pseudostratified vomeronasal epithelium, while the second ones are found in the more basal strata. The joined patterns of expression indicate that all mature sensory neurons express either V1r or V2r genes.

4.44.2.5 V1rs as Chemodetectors and Guidance Molecules

A remarkable dual role is apparently played by V1r receptors. First, not surprisingly, those expressed at the vomeronasal dendritic endings in contact with the outside world, play a role in chemodetection. This is supported by

1. a genetic approach in the mouse involving the deletion of an entire V1r cluster, and the observation of a correlated deficiency to perceive pheromones *in vitro*, and of inadequate behavior responses to specific interindividual interactions (Del Punta, K. *et al.*, 2000; Del Punta, K. *et al.*, 2002), and
2. by the identification of 2-heptanone, a molecule present in mouse urine, which plays a pheromonal role in this species, as an agonist for the V1rb2 receptor (Boschat, C. *et al.*, 2002).

Second, the expression of V1rs is instrumental in the elaboration of an adequate topographical map in the accessory olfactory bulb. Genetic experiments have shown that vomeronasal sensory neurons expressing a given V1r gene project their axons toward 10–20 neuropil-rich spherical structures, called glomeruli, in the caudal part of the olfactory bulb termed the accessory olfactory bulb (Belluscio, L. *et al.*, 1999; Rodriguez, I. *et al.*, 1999). Sensory neurons expressing other V1r receptors project to different glomeruli, leading to a complex topographical map of a few hundred glomeruli. The prevention of expression of a given V1r in a sensory neuron population leads to an altered axonal projection map, no longer convergent, which innervates glomeruli corresponding other receptors. This very particular dual role is also shared by odorant receptors, receptors that can even substitute for V1rs, in a vomeronasal context (Rodriguez, I. *et al.*, 1999). This and other observations in the olfactory system (Feinstein, P. *et al.*, 2004) suggest that very unrelated seven transmembrane receptors, in different systems, may also play a role in axonal targeting.

4.44.3 V2r Receptors

Three research groups independently identified V2rs in 1998 (Herrada, G. and Dulac, C., 1997; Matsunami, H. and Buck, L. B., 1997; Ryba, N. J. and Tirindelli, R., 1997). Our understanding of V2r biology, both in terms of role and expression in different species, lags behind the little we know about V1rs, likely for the simple reason that their identification postdates the one of V1rs. Unlike these latter, V2rs share strong homologies with well-known seven transmembrane G-coupled receptors, with long extracellular N-termini, including calcium-sensing and glutamate receptors.

4.44.3.1 Genomic Parallels and Divergences with V1rs

V2r genes have been identified in vertebrates, and are apparently restricted, as V1rs, to this subphylum. Numerous V2rs are found in frogs (Hagino-Yamagishi, K. *et al.*, 2004), and in teleost species (Cao, Y. *et al.*, 1998; Naito, T. *et al.*, 1998; Speca, D. J. *et al.*, 1999; Hashiguchi, Y. and Nishida, M., 2005), such as *Danio rerio*, for example, whose genome contains over 50 V2rs, (contrasting with the extremely limited number of V1rs in this species). In mammals such as mice and rats, 61 and 57 V2r genes with intact open reading frames have been reported, respectively (Yang, H. *et al.*, 2005). These numbers represent a strikingly low proportion (between 29% and 34%) of the complete, pseudogene-including V2r repertoire of these two species. The chromosomal distribution of these genes is wide, since in the mouse they are located on at least 12 chromosomes, including the X chromosome. V2rs tend, like V1rs, to be clustered in the genome, with no apparent specific organization within these clusters.

The exact number of different expressed receptors corresponding to the known V2r genes is difficult to evaluate, since the large extracellular part of V2r receptors is encoded by multiple exons that are often alternatively spliced, and which therefore lead to a corresponding expansion of the V2r

repertoires variability. In rodents, V2rs have been classified into three families, among which one, family C, is particularly distant from the others, a situation likely reflecting an ancient divergence with the other two families, predating the separation between teleosts and tetrapods (Yang, H. *et al.*, 2005). Repertoire comparisons between mouse and rat indicate that similarly to what is observed for V1rs, V2rs form species-specific clades, with the result that only a few rat–mouse orthologs can be identified. A more detailed analysis of the evolution of rodent V2rs suggests that most species-specific clades resulted from recent gene duplications/losses, with a minor role played by gene conversion events. Moreover, similarly to what was observed for V1rs, positive selection was detected for specific amino acids in V2rs (Yang, H. *et al.*, 2005), with the particularity that most of them were located on the N-terminal extracellular region of the receptor, a segment thought to mediate ligand/receptor interactions.

4.44.3.2 Immune Multigene Families and V2r-Expressing Sensory Neurons

Vomeronasal receptors are thought to interact with G proteins, respectively, the Gi2a and Goa subunits for V1rs and V2rs. An unexpected complex and nonrandom coexpression, and interaction, was recently reported between two unlikely partners: V2r receptors and major histocompatibility complex (MHC) molecules (Ishii, T. *et al.*, 2003; Loconto, J. *et al.*, 2003). Members of the nonclassical MHC class I M10 and M1 families (6 and 3 members, respectively), are exclusively expressed by vomeronasal sensory neurons. Genes encoding for these receptors are clustered on chromosome 17 in the mouse, and are part of the H2-M locus, the most distal segment encoding class I genes.

These MHC receptors are involved, via a still unknown mechanism, in the adequate export of at least some V2rs to the cellular membrane (Loconto, J. *et al.*, 2003). Reports suggest however, in addition, a more direct involvement of MHC molecules in pheromone perception. For example, MHC-diassortative pregnancy block and preferences have been demonstrated in multiple species and conditions. Moreover, some vomeronasal sensory neurons respond to class I, MHC-binding peptides (Leinders-Zufall, T. *et al.*, 2004). The presence of specific MHC molecules in the vomeronasal organ forces us to consider them as prime candidates for such interactions. Thus, it is possible that not only do MHC type I function as facilitators of V2r cell surface expression, but that they may be able to detect peptides (although crystal structure data does not support this hypothesis (Olson, R. *et al.*, 2005)) via the use of their binding grooves, a crucial tool used by their classical counterparts.

4.44.4 Perspective

4.44.4.1 A Genomic Trail of Speciation Events

A similar strategy has thus been selected by evolution to provide vertebrate pheromone-sensing systems with two large and diverse repertoires of chemoreceptors: rapid gene birth and death. We look today at a battlefield with hundreds of pseudogenic sequences, often more numerous than potentially functional ones. This represents an amazing source of information, and because of the speed at which the repertoires evolved, a unique recording of speciation events, including those that occurred relatively recently. We are now lacking data relative to the other side of the coin: the pheromones themselves. These are today, in vertebrates, still remarkably poorly described (insects got somehow more attention for once). Even in rodents, which are largely the best-studied mammals in the pheromone field, <10 compounds have been reported to mediate pheromonal interactions, a situation largely due to the tedious biochemical purifications involved in the identification of these chemicals. Thus, unless we benefit from a biochemical technical revolution allowing large-scale approaches similar to the one which makes today a quick survey of complete genomes an easy task, a global understanding of vertebrate pheromone perception at the peripheral level will be incomplete, for a long time.

Glossary

2AFC Two-alternative forced-choice psychophysical paradigm in which a subject must choose which of two alternatives (one target and one distracter) is the target.

3AFC Three-alternative forced-choice psychophysical paradigm in which a subject must choose which of three alternatives (one target and two distracters) is the target.

adaptation The temporary diminution of response to successive repetitions of a stimulus.

adaptive staircase method A method for presenting stimuli to ascertain a detection threshold in which the choice of successive stimuli depends on prior responses.

anosmia A condition in which a subject cannot detect any odorant.

anosmia, specific An inability to detect a specific odorant in the absence of a general anosmia.

ascending method of limits A method for presenting stimuli in sequence from low to high concentration to determine detection threshold.

detection threshold The minimal concentration of an odorant sufficient for reliable detection.

JND Just noticeable difference. The smallest increment in the intensity of a stimulus that can be discerned.

magnitude estimation The assignment of a numerical value to the perceived intensity of a stimulus

MDS Multidimensional scaling. A technique for inferring a coordinate space in which objects whose pairwise distances are known can be placed.

method of constant stimuli A procedure for determining absolute or discrimination thresholds wherein a standard stimulus is presented repeatedly against distractors drawn one at a time from a set spanning a range of intensities and subjects make a forced-choice decision at each trial.
odorant Airborne molecule perceived as an odor.
olfactometer A device for the precise delivery of odorants to a subject.
osmic Able to smell, in contradistinction to anosmic.
power law A mathematical function that describes the relationship between a stimulus magnitude and its corresponding perceived magnitude.
psychometric function A function that relates a behavioral response (e.g., percent correct identification) to a stimuli to some parameter (usually a magnitude) of the stimulus.
psychophysics The precise measurement of perceptual phenomena in relation to their physical stimuli.
pure olfactant An odorant that activates only the olfactory and not the trigeminal system
signal detection theory A theory that describes how well a signal can be detected embedded within noise as a function of the signal strength and the detector's criterion or bias.
trigeminal odorant An odorant that stimulates the trigeminal system.
UPSIT University of Pennsylvania smell identification test. A standardized multiple-choice smell identification test that is used to identify olfactory function as a function of age.
vibrational theory A controversial theory of how molecules interact with olfactory receptors according to which receptors use a form of electron spectroscopy to measure the vibrational spectra of molecules.
Weber–Fechner law A law which states that the perceived magnitude of a stimulus is proportional to the logarithm of the intensity of the stimulus.
Weber fraction The minimal increment in a stimulus necessary to perceive a change. It is a constant proportion of the original comparator stimulus.

4.45.1 Introduction

The field of psychophysics deals with describing the relationship between physical stimuli and their resultant perceptual phenomena within a rigorous, quantifiable framework. The field of neuroscience is then tasked with elucidating the genetic, molecular, cellular, and system-level physiological mechanisms that underlie this psychophysical framework. This pattern whereby psychophysics guides physiological research has been central to our understanding of the physiology of vision and audition. For example, psychophysical studies in vision demonstrated that all perceived colors can result from the mixing of just three colors, and that these perceived colors are largely determined by the wavelength of the impinging light. This psychophysical trichromatic model of color perception was the impetus that guided physiologists in their discovery of the three receptor types in the retina that provide the basis for color perception (De Valois, R. L. and De Valois, K. K. 1993).

Similarly, olfactory psychophysics has provided a broad basis for understanding olfaction. Often, however, what is observed about olfactory psychophysics is not the great mass of knowledge, but rather one prominent lack: the core question in olfactory psychophysics, namely, which particular properties of airborne molecules give rise to particular odor qualities, remains unanswered. The reason for this lacuna is not, as we shall see in this chapter, want of industry, but rather the peculiar complexities of both the stimulus and the perceptual response. Sometimes characterized as the most primitive sense, olfaction has also proved itself to be the most stubbornly inaccessible. Undoubtedly, this is in part because the stimulus is more complex than that in other distal senses. In vision, three spatial dimensions, one of intensity and another of wavelength, do much to constrain the stimulus space. In audition a similar number of dimensions are sufficient to characterize the basic properties of the stimulus. In olfaction, the number of stimulus features necessary to characterize the countless discriminable odor molecules may well number in the hundreds, and so olfaction may well be orders of magnitude more intrinsically complex than the other distal senses. Notwithstanding all this, a

considerable body of psychophysics exists and provides important constraints on efforts to understand olfactory physiology.

Olfactory perception can be described as a hierarchical pyramid (Savic, I. *et al.*, 2000) building up from a base of olfactory detection, followed by olfactory discrimination, and culminating in olfactory identification. We consider these three levels of processing as hierarchical because of their pattern of exclusivity. One can have olfactory detection without olfactory discrimination and identification, but not vice versa. Likewise, one can have detection and discrimination between two odorants, without odorant identification. Finally, olfactory identification requires olfactory detection, implicitly entails olfactory discrimination, and represents the highest level of olfactory processing whereby an olfactory percept is matched to an olfactory memory and given a semantic label. In this chapter, we will use this hierarchy of olfactory processing as our organizational guide and describe what the psychophysical study of human olfaction has taught us regarding each of these three processing stages.

It is noteworthy that the above functional hierarchy is loosely related to a neuroanatomical structural hierarchy (Savic, I. *et al.*, 2000; Royet, J. P. *et al.*, 2001; Sabri, M. *et al.*, 2005). The first phase in olfactory processing consists of sniffing odorants (reviewed in Mainland, J. and Sobel, N. 2005) that then cross a mucous membrane (reviewed in Lewis, J. E. and Dahl, A. R. 1995) in order to interact with (in humans) ~14 million olfactory receptors of ~400 different types (Gilad, Y. and Lancet, D. 2003) that line the olfactory epithelium. Same receptor types then converge via the olfactory nerve onto unique locations in the olfactory bulb called glomeruli. Following some processing at the level of the olfactory bulb, information is conveyed via the olfactory tract to olfactory cortex, mostly inhabiting the ventral portion of the temporal lobe (reviewed in Price, J. L. 1990). From there, olfactory information is relayed throughout the brain to multiple sites, most notably the limbic system, the orbitofrontal gyri, and insular cortex (reviewed in Sobel, N. *et al.*, 2003).

The process of olfactory detection is largely linked to events at the level of the epithelium in that it reflects a nonspecific increase is system activation beyond noise levels. The process of olfactory discrimination is linked to both events at the epithelium and events in the bulb, in that it reflects specific rather than nonspecific patterns of activity. Discrimination is also linked to cortex in that it calls upon short-term memory (Wilson, D. A. and Stevenson, R. J. 2003a; 2003b). Finally, the process of olfactory identification is linked to events in the epithelium and bulb, and strongly linked to events in cortex, in that it reflects linking specific patterns of odorant-induced activity to previously stored information such as semantic representations (Haberly, L. B. and Bower, J. M. 1989; Stevenson, R. J. and Boakes, R. A. 2003). Some human lesion studies support this loose link between the structural and functional hierarchy of olfaction. For example, temporal lobe lesions hamper olfactory discrimination and identification, but not detection (Zatorre, R. J. and Jones-Gotman, M. 1991). This link, however, should be treated as a loose framework only, as even the basic process of olfactory detection is undoubtedly subserved by cortical mechanisms of attention and noise suppression.

Although in this chapter we will focus on basic psychophysical mechanisms, it is noteworthy that these basic mechanisms subserve an extraordinary human sense (Shepherd, G. M., 2004). Humans have superb olfaction. For example, it may not surprise many that dogs can recognize humans by their odor (Schoon, G. A. A. and Debruin, J. C., 1994), but it will probably surprise most that reciprocally, humans can identify dogs by their odor (Wells, D. L. and Hepper, P. G., 2000). Similarly, the dominance of olfactory cues in the interaction between a rabbit and its pups is common knowledge (Schaal, B. *et al.*, 2003), but not all are aware that human mothers can identify their babies by smell (Porter, R. H. *et al.*, 1983), and human babies can identify the smell of their breast-feeding mother by 6 days after birth (Macfarelane, A. 1975; Schaal, B. *et al.*, 1980). Finally, that a pig can locate a truffle by its smell (Ackerman, D., 1990) is appreciated by all who like to eat it (the truffle), but that humans can spatially localize an odorant in a laboratory setting (Békésy, G. V. 1964; Porter, J. *et al.*, 2005) (Figure 1), or track an odor trail in a field setting (Porter, J. *et al.*, 2007), is appreciated by only an esoteric few. These are only but a few of the extraordinary olfactory abilities of humans.

Finally, despite the temptation of digressing to relevant data from physiology and functional imaging, as well as data from nonhuman animals, in this chapter we will limit such excursions to the absolute minimum. Here, we concentrate on human olfactory psychophysics only, but we encourage the interested reader to pursue the relevant physiology and imaging literature.

Figure 1 Scent tracking in dogs and humans. The left panel consists of an image published in the 1978 National Geographic Survey on Smell. A dead pheasant was dragged along a field as denoted by the yellow line. A dog with light-emitting diodes on its collar was then released at the far end of the field. The time-lapsed image reveals the dog's tracking behavior. The right panel consists of data from ongoing experiments in our laboratory. The odorant track was made of a mixture of common odorants. All sensory input other than olfaction was prevented by opaque goggles, earmuffs, and thick gloves. A backpack was equipped with monitors that measured subject's nasal respiration in real time and monitored subject location with RTK-GPS offering 1 mm resolution. Although slow, human subjects were surprisingly good at tracking scent trails.

4.45.2 Olfactory Detection

A basic idea of psychophysics is that there is a minimum stimulus quantity that is needed for conscious perception of a sensory event (Herbart, J. F., 1824–1825). In olfaction, estimates of this minimal quantity vary across odorants and even for the same odorant have varied tremendously across laboratories (Laffort, P. 1963; Patte, F. *et al.*, 1975; Van Gemert, L. J. and Nettenbreijer, A. H., 1977; Fazzalari, F. A., 1978; Van Gemert, L. J. 1984). For example, Amoore J. E. and Hautala E. (1983) report 10^6-fold range in detection threshold across laboratories for some odorants. This state of affairs, understatedly described by Devos M. and Patte F. (1990) as disappointing, is mostly the result of several clearly understood extraneous sources of variance having to do with methods of stimulus generation and delivery. Thus, any reading of the olfactory psychophysics literature depends on an understanding of these extraneous sources, which we will first review.

4.45.2.1 Method of Odorant Delivery

4.45.2.1.1 Olfactometers

In an otherwise excellent review of olfactory psychophysics, Engen T. (1973) noted that "[a] great deal has been done recently in instrumentation of the presentation of odorants, enough surely to satisfy those who feel psychophysical research starts with the apparatus." Yet 30 years after this perhaps too optimistic appraisal, we find that there is still no uniform standard device for the delivery of odorants. Odorant delivery methods vary widely across laboratories, and even in those that expend the most effort (and funds) toward odorant generation, there is still no olfactory device on a par with the visual projector or auditory amplifier.

The two most commonly used methods of odorant delivery are either sniffing the headspace over an odorant-filled jar or delivery through a dedicated apparatus usually referred to as an olfactometer, a term coined by Hans Zwaardemaker, one of the first to build such a device (Zwaardemaker, H., 1889). Olfactometers range from simple devices such as squeezable bottles fitted with nose cones, to slightly more complex devices using solenoid valves to control odorized airflow, to sophisticated devices using computer-controlled mass flow controllers (MFCs) that allow for precise control over not only odorant concentration, but also timing, temperature, and humidity (reviewed in Prah, D. *et al.*, 1995). See Figure 2 for an example of such an olfactometer and associated imaging and psychophysics uses.

Regardless of complexity, most olfactometers odorize the airflow by flowing a carrier (clean air or nitrogen) either over an odorant within a canister of some sort or through an odorant-infused sponge-type media, or bubbling the carrier through liquid odorant in a canister. The latter enables obtaining higher overall concentrations of odorized airflows, but carries the risk of generating aerosols within the odorized airflow. Thus, flowing carrier over, rather than through the odorant, generates a far more stable stimulus and is the recommended approach whenever it is sufficient for generating a dynamic range of concentrations. Most current olfactometers are air-dilution olfactometers, which means that they obtain the intended odorant concentration by diluting an odorized airflow with a clean airflow. The ratio of dilution will determine the end concentration. This stands in contrast to simpler olfactometers in which the concentration of the resultant airflow is set by using different concentrations of odorant liquid within the odorant canisters. High-end air-dilution olfactometers also enable mixing different odorized airflows with each other in order to obtain air-dilution odorant mixtures. MFC-equipped olfactometers offer the highest level of control over airflow parameters, enable odorant delivery onset times within the millisecond range, have very high repeatability and stability, and when properly calibrated with analytical devices such as photoionization or flame-ionization detectors, offer accurate control over odorant concentration. Although all the above attributes of high-end

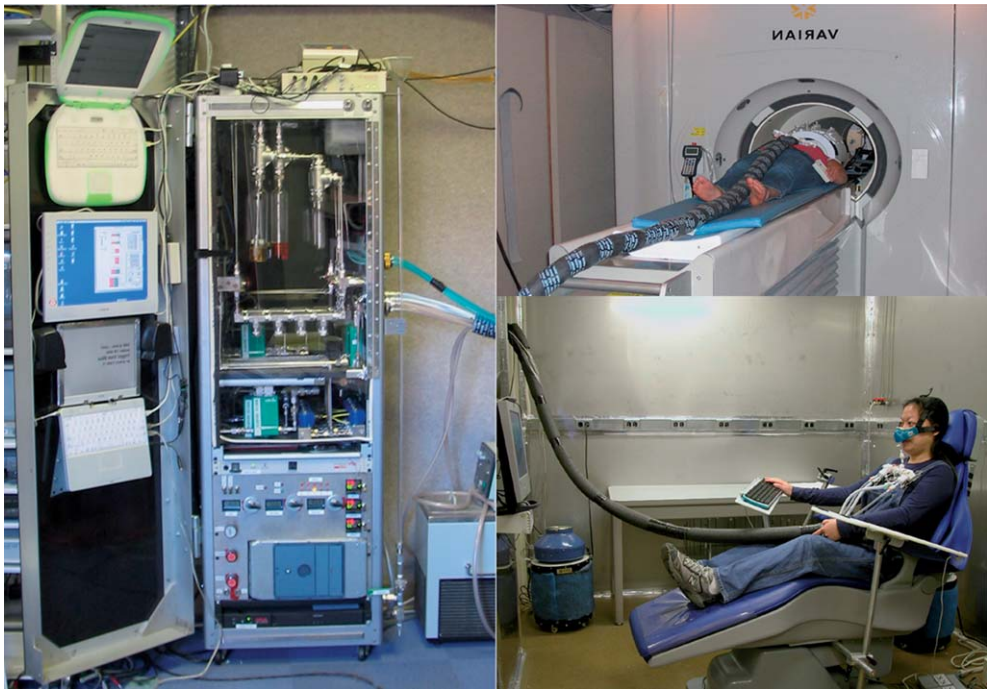

Figure 2 An air-dilution olfactometer. The olfactometer (left panel) is about 6 × 2 × 2 feet and weighs about 400 lbs. Using 13 MFCs and 18 solenoid valves, it delivers odorants to subjects in either the psychophysics laboratory (bottom right panel) or the fMRI scanner (top right panel) while simultaneously measuring airflow in each nostril separately. Although the olfactometer controls odorant temperature, humidity, flow rate, identity (one of five odorants, or any binary mixture thereof), intensity (verified by photoionization), and temporal resolution to the order of ~2 ms, it is still a far cry from a visual projector or auditory amplifier in its accuracy and versatility.

olfactometers render them the likely candidate for generating odorant stimuli when measuring absolute olfactory detection thresholds, these devices also suffer from typical drawbacks that hamper such efforts. Most prominent of these drawbacks is contamination. Within an olfactometer, odorized air passes through tubing before it reaches the sampling port, which may be in the form of a nasal mask, or tubes (canulas) that are inserted into the nostrils. Odorant molecules from ongoing experimental events tend to stick to these tubes, and then present themselves at unwanted times. Such contamination can be minimized by using nonstick tubing materials such as Teflon, glass, and stainless steel, but the contamination cannot be altogether eliminated. Considering the outstanding sensitivity of the human olfactory system, such contamination renders olfactometers a problematic device for the determination of absolute detection thresholds. Olfactometers remain, however, the preferred method of stimulus delivery for other olfactory tasks such as suprathreshold magnitude estimation, olfactory discrimination, identification, and so on.

4.45.2.1.2 To sniff or not to sniff

Olfaction is strongly dependent on a sensory-motor component, namely sniffing (Mainland, J. and Sobel, N. 2005). When using an olfactometer, one can eliminate sniffing by injecting the odorant into the nostrils of an otherwise passive subject. Furthermore, the subject can be trained in the behavior of velopharyngeal closure, whereby the soft palate elevates and lateral pharyngeal walls move medially to meet the soft palate to separate oral and nasal cavities, a method developed to reduce sniff-related artifacts that may be present in various methods of recording neural activity (Kobal, G. and Hummel, C., 1988). However, in most psychophysical studies, preventing sniffing significantly alters the behavior under investigation. Sniffs transport approximately 5–10% of the airflow entering the external nares to the epithelium (Keyhani, K. *et al.*, 1997). Sniff airflow velocity influences olfactory detection thresholds (Le Magnen, J., 1945; Laing, D. G., 1983; Sobel, N. *et al.*, 2000a) and olfactory intensity estimates (Rehn, T., 1978; Teghtsoonian, R. and Teghtsoonian, M., 1984; Youngentob, S. L. *et al.*, 1986; Hornung, D. E. *et al.*, 1997). Moreover, the somatosensory stimulation associated with airflow in the nose is represented by neural activity in both human olfactory bulb (Hughes, J. R. *et al.*, 1969) and olfactory cortex (Sobel, N. *et al.*, 1998), and it is necessary for olfactory perception. For example, when an odorant is injected intravenously into the bloodstream reaching the olfactory epithelium, it is not perceived as an odor. However, if the injection is simultaneously accompanied by a sniff of odorless air, or by a puff of odorless nitrogen into the nose, it is perceived as odor (Engen, T., 1973). In fact, a sniff may be sufficient to generate a rudimentary olfactory percept even in the absence of odorants. For example, when an early-type olfactometer that injected puffs of air into the nose (blast olfactometer) was tested, subjects responded to the blast pressure as an odor, even when odorant was not present (Wenzel, B. M. 1949; 1955). Similarly, when humans try to imagine an odor, they spontaneously sniff (Bensafi, M. *et al.*, 2003b), and if this spontaneous sniffing is prevented, the vividness of their olfactory imagery is reduced (Bensafi, M. *et al.*, 2005). All of this goes to show that sniffing is an integral and essential part of olfaction, and thus, when measuring olfactory behavior, sniffing should be enabled and measured whenever possible, even if it is avoidable through cannulated olfactometry.

4.45.2.1.3 Jars

An alternative to olfactometers is odor delivery by jars. Here the odorant is presented to the subject by smelling the headspace over a glass jar containing odorant at a given concentration, or by smelling the resultant airflow from a squeeze bottle similarly containing a fixed concentration of odorant. One can point to several disadvantages of this method in comparison with an olfactometer. In a high-end olfactometer equipped with an analytical device such as photoionization or flame ionization one has a dependable measure of odorant concentration in the vapor smelled by subjects. In contrast, when using jars, one can only estimate odor concentration based on the ideal gas law and Henry's law that assume proportionality of concentration in the headspace above a solution to the molar fraction within the solution. Unfortunately, due to various parameters such as interactions of the odorant with the diluents (e.g., mineral oil), the headspace concentration over a jar does not always match the theoretical expected concentration. Stone H. (1963) analytically measured the concentration of propionic acid within a mineral oil-based dilution series in jars and found that the actual headspace concentration deviated from the expected concentration, as deduced from the ideal gas law and Henry's law, by as much as two orders of magnitude (Stone, H., 1963; Haring, H. G. *et al.*, 1972). This limitation may be overcome by somehow

incorporating an analytical sampling protocol from jar headspace during jar delivery. However, besides the technical impracticality of such a solution, it would still not assure a controlled stimulus concentration. This is because factors such as variable distance of jar from nose across trials and across subjects, as well as variable sniffing behavior (Pfaffmann, C. 1951; Cain, W. S. and Engen, T. 1969), will all influence end concentrations. Jars have additional shortcomings in comparison with an olfactometer in the context of threshold testing. Whereas an air-dilution olfactometer can produce a very large number of discrete odorant concentrations, when using jars, one must have a separate jar for each concentration. This either limits the number of concentrations one can test, or requires use of many jars, a cumbersome arrangement indeed. In our experiments, we typically use ~25 jars in the process of a single odorant threshold determination. All that said, despite these and other drawbacks, the issue of olfactometer contamination renders jars the preferred method in our view for testing absolute detection threshold. Even having settled on jars another complication still looms large. When using jars, comparisons across groups (e.g., patients vs. healthy controls) or individuals within a laboratory are possible, but comparisons across laboratories are limited. Different laboratories use different type jars, different ratios in their dilution series, different diluents, and different methods for presentation of jar to nose. A solution that may minimize this variance may be found in two threshold test kits that have recently been made commercially available. One kit uses jars for presentations (The Smell Threshold Test, Sensonics) and the other uses odorant-pens (Sniffin' Sticks, Burghart Medical Technology) (Hummel, T. *et al.*, 1997; Kobal, G. *et al.*, 2000). Although these kits promise some uniformity across laboratories, they are each limited to one odorant, have rather widely spaced concentration intervals, and are expensive. An alternative to the commercial solution is for olfactory psychophysicists to finally agree on standards they will all use. The foundation for such an effort can be found in the work of groups such as Walker and colleagues (Walker, J. C. *et al.*, 2003) or Cometto-Muniz and their colleagues (Abraham, M. H. *et al.*, 2002; Cometto-Muniz, J. E. *et al.*, 2002; 2003), who have meticulously measured detection thresholds for many odorants (Cometto-Muniz, J. E. and Cain, W. S. 1990; Cometto-Muniz, J. E. *et al.*, 1998a; 1998b; 2001; 2002; 2003), and more critically, have described the relationship between liquid-phase and vapor-phase concentrations for many odorants (Cometto-Muniz, J. E. *et al.*, 2003).

4.45.2.2 The Assumed Threshold Model

Regardless of whether delivering odorants with olfactometers or jars, determination of detection threshold depends on the application of a particular sampling methodology and statistical criterion. In general, one assumes that detection around the threshold concentration conforms to a psychometric function, typically an S-shaped or ogive function wherein stimulus detectability increases continuously from chance to perfect accuracy over a range of stimulus concentrations. Such psychometric functions are prevalent across sensory modalities, and a typical example is shown in Figure 3. In the figure, stimulus intensity (concentration) is plotted on the abscissa and the observer's performance in a two-alternative forced-choice (2AFC) procedure is plotted on the ordinate. In this context, the observer's threshold is defined as some level of detectability, typically midway between chance and perfect performance, corresponding to 75% performance in the figure. Different procedures will define threshold at different levels of performance, accounting for some of the variance in results reported in the literature.

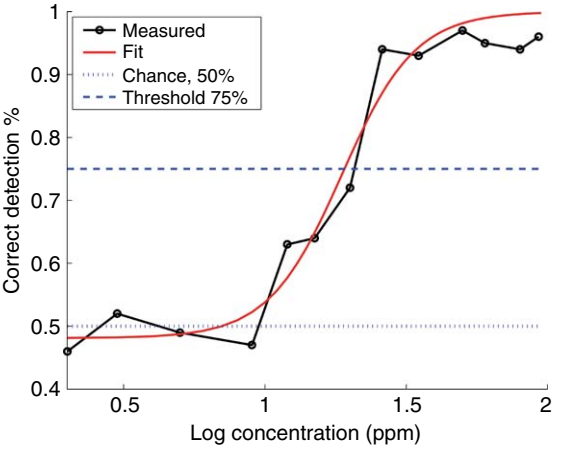

Figure 3 Detection threshold. Detection performance (percent correct in a two-alternative forced-choice (2AFC) task) is plotted as a function of odorant concentration. Raw data (black curve) are fitted with a Weibull psychometric function (red curve) which is used to determine the threshold detection value (value of the red curve at 75% correct performance; in this case ~1.3 log[ppm]). The use of a fitted curve allows more precise determination of thresholds than the raw data, which often has a fixed arbitrary step size.

A second source of variance is observer bias. An observer's response in the context of a threshold test is the product of (at least) two components, a sensory component reflecting the neural activity induced by the stimulus and a psychological component or bias reflecting the observer's predisposition to give one reply or another. This bias is usually different across observers and can also be modified by changing the task structure. For example, bias towards one response or another can change dramatically as a function of task contingencies, that is, the cost associated with making an error versus the benefit of making a correct selection. Methods of signal detection theory have been developed to control the influence of psychological bias on deduced detection thresholds. It is important to note, however, that complete disentanglement of these processes may be impossible, because psychological bias may influence not only the report of a sensory process, but also the sensory process itself. This is particularly true for olfaction that is typified by robust centrifugal projections from central brain structures to the periphery (Luskin, M. B. and Price, J. L., 1983). For example, the expectation of odor modifies patterns of neural activity in the olfactory bulb (Kay, L. M. and Laurent, G., 1999) and olfactory cortex (Zelano, C. *et al.*, 2005); thus, the bias of expectation will modify the sensory process of detection. With these issues in mind, we review methods for determining detection thresholds below.

4.45.2.3 Measuring the Threshold Model

The most widely used methods for measuring olfactory thresholds are the ascending method of limits (AML) (Cometto-Muniz, J. E. and Cain, W. S., 1998) and the adaptive staircase method (Dixon, W. J. and Massey, F. J., 1957; Cornsweet, T. N., 1962). A third method called the method of constant stimuli, which has been used in other sensory modalities, has been rarely used in olfaction, as the relatively large number of trials required by this method combined with the relatively large interstimulus intervals (ISIs) in olfaction make it prohibitive in most situations (Cain, W. S. *et al.*, 1988). In the AML, a sequence of concentrations of the odorant around the probable threshold concentration are prepared and trials are presented in sequence starting from the lowest and proceeding to the highest. Each trial consists of a 2AFC in which subjects are presented with the target odorant mixed in diluent and with just the diluent and are forced to indicate which of the two contained the odorant. If the subject is correct, another trial at the same concentration is initiated. If the subject is incorrect, the next highest concentration is used. The procedure is terminated when a predetermined number (typically five) (Cometto-Muniz, J. E. and Cain, W. S., 1998) of successive correct trials is achieved. Detection threshold is typically defined as the last concentration used.

The adaptive staircase is similar to the AML in that it too samples a predetermined series of concentrations with a 2AFC per trial procedure but differs in how it samples these concentrations and in its stopping rule. The staircase may be started at any trial, typically one is randomly chosen above the expected threshold, and then a rule is applied after each trial which determines the next concentration to use. In a typical staircase, a one-up two-down rule is used which means that after one incorrect trial the next highest concentration is used, and after two successive correct trials, the next lowest concentration is used. After a single correct trial, the same concentration is sampled again. Typical stopping rules for staircases include a predetermined number of sampling reversals, or a predetermined number of total trials (Linschoten, M. R. *et al.*, 2001). The data from the staircase are used to fit a psychometric function, typically an S-shaped function such as a logistic, cumulative normal, or Weibull function (see Figure 3). Threshold is defined as the concentration derived from the fitted function corresponding to performance halfway between chance and perfect performance, which is 75% correct in the case of a 2AFC. It should be noted that this definition of threshold differs from that used in the AML, which defines threshold as 100% performance, which explains why thresholds using AML are typically higher than those using staircases.

A variant of the adaptive staircase is the maximum likelihood adaptive staircase method (MLASM) in which a psychometric function is fit to all the data collected thus far after each trial, the threshold is estimated from this fitted function, and a concentration close to it is chosen for the next trial (Taylor, M. M. and Creelman, C. D., 1967). A number of procedures of MLASM are available (Linschoten, M. R. *et al.*, 2001). The method described by Linschoten M. R. *et al.* (2001) uses a logistic-function psychometric model and uses a sufficiently small error estimate on the estimated threshold as a stopping criterion. Their method compares favorably in terms of expected stopping time and accuracy of the estimated threshold with a one-up two-down staircase

method, and both methods outperform AML. It should be noted that this result is partly due to the different definitions of threshold employed, and because the AML method uses only a few data points rather than the whole set to estimate threshold. Indeed, when the same logistic function is fitted to the data collected from AML, i.e., when all the data collected are used to estimate the threshold rather than just the last few data points, the thresholds derived from the fit agree well with those derived from the staircase and MLASM methods (Linschoten, M. R. *et al.*, 2001). These results suggest that the method of sampling data around the threshold is less important than how this data are analyzed, i.e., when a proper psychometric function is fitted to the data and a common definition of threshold is applied (75% correct), all three methods are about equally useful. Indeed, using the AML procedure, while having the advantage of providing a threshold without recourse to computation, has little justification given the artificially large error of the method, and the trivial effort involved in significantly improving it. When a psychometric function is fit to all the data, the most significant factor in the precision of the estimated threshold is not the method of sampling concentration steps, but the step size between them (Linschoten, M. R. *et al.*, 2001). Considering all of the above, we recommend using the MLASM method and further recommend using the convenient shareware software available for this purpose called MLpest.

4.45.2.4 Measuring Near-Threshold Performance

Although determining a threshold concentration for detection or recognition is the most common question in research, a somewhat different procedure is needed to answer questions about near-threshold detection performance. In questions of absolute detectability, such as for example, whether a subject can truly detect the presence of a compound he or she appears to have no percept for, one might wish to use a procedure that explicitly incorporates a decision behavior model. The simplest and most widely used such procedure is derived from signal detection theory (Tanner, W. P. and Swets, J. A., 1954; Green, D. M. and Swets, J. A., 1966). In this model, the subject is presented with a large number of trials consisting of a single sample that either contains just the diluent or the diluent plus an odorant at some fixed concentration. The subject must indicate on every trial whether an odorant was present or not (yes or no). This results in four kinds of stimulus-response situations, which are conventionally called hits (stimulus present, yes), misses (stimulus present, no), correct rejections (stimulus absent, no), and false alarms (stimulus absent, yes). In this situation, different subjects may have different decision criteria or biases: a conservative subject may only indicate that the odorant is present only when he or she has high certainty resulting in relatively more misses and fewer false alarms, whereas a less conservative subject will indicate the presence of the odorant with significantly less certainty, resulting in relatively more false alarms and fewer misses. Signal detection theory provides a model of subject behavior that explicitly includes terms for the discriminability of the odorant from the diluent (termed d-prime), and for the subject bias or degree of conservatism (termed beta). These parameters are separable and subject to different manipulations: changes in the concentration of the olfactant will change d-prime, whereas differences in the rewards and penalties associated with correct and incorrect responses will change beta. Thus, subject bias may be factored out when discriminability is the issue, or conversely may be focused upon when it is the question of interest.

An example of the use of signal detection is found in a study by Bremner E. A. *et al.* (2003) in which eight putative nondetectors of the steroidal compound androstenone were tested on 74 yes/no detection trials. Although these putative nondetectors were determined to be insensitive to androstenone in a screening study, d-prime analysis of their yes/no trials revealed that seven of eight putative nondetectors could in fact detect androstenone. A second example from Sobel N. *et al.* (1999) found that eight subjects who reported no odor percept for a variant of the steroidal compound androstodienone were able to detect it in a signal detection experiment.

4.45.2.5 Nonolfactory Detection of Airborne Chemicals

The perception of smell is the result of odorant transduction at several types of nerve-endings, which will often occur in concert (Bojsen-Moller, F., 1975). An odorant that enters the nasal passage can stimulate both cranial nerves I (olfactory) and V (trigeminal), and most known odorants stimulate both. However, sensitivity and specificity are greater in the olfactory than the trigeminal nerve, and the latter conveys primarily nasal irritation (Cain, W. S.

and Murphy, C. L., 1980; Hummel, T., 2000). In this respect, the trigeminal system may serve as a nonspecific chemical warning device, rather than assist in olfactory discrimination and identification. There is some debate in the literature as to which odorants are pure olfactants, that is, stimulate the olfactory nerve only. There is, however, general agreement that vanillin is such an odorant (Doty, R. L. *et al.*, 1978; Doty, R. L., 1995). The odorants hydrogen sulfide, phenyl ethyl alcohol (PEA), and decanoic acid are also considered to have minimal trigeminal stimulation, if any (Doty, R. L. *et al.*, 1978; Livermore, A. *et al.*, 1992; Doty, R. L., 1995). By contrast, carbon dioxide can be considered a pure trigeminal in that it stimulates the trigeminal but not olfactory nerve (Hummel, T. *et al.*, 2003). Although most odorants will stimulate both systems, trigeminal thresholds are often several orders of magnitude higher in concentration than olfactory thresholds for the same odorants (Cometto-Muniz, J. E. and Cain, W. S., 1990). Thus, degree of trigeminal activation will have little influence on results of detection threshold studies, but may have significant impact on the results of studies using suprathreshold concentrations.

4.45.2.6 Adaptation

Any consideration of reported olfactory detection thresholds must consider the phenomenon of adaptation. Adaptation, in all sensory systems, is the waning of response with stimulus repetition. Adaptation can be viewed as either a limitation or advantage in sensory processing. It is a limitation in that the adapted sense may be unable to register the occurrence of an event that closely followed a previous, adapting event. By contrast, adaptation functions as gain control within sensory systems. This enables the system to detect changes under conditions of vastly differing background levels. Olfactory adaptation may result from mechanisms at every level of the olfactory process, starting from molecular mechanisms at the level of olfactory receptors, and on to cellular mechanisms at the level of olfactory bulb and cortex (Sobel, N. *et al.*, 2000b; Poellinger, A. *et al.*, 2001). Olfactory adaptation was first demonstrated by Zwaardemaker H. (1895) who found that during constant olfactory stimulation, detection threshold decreases linearly (Pfaffmann, C. 1951). Thus, in the context of determining absolute olfactory detection thresholds, one must consider adaptation in the experimental design. Specifically, an early trial within the threshold test may influence the outcome of the next trial. To minimize this, one must take the following two steps. Considering that adaptation is increased following exposure to higher concentration odorants (Berglund, B. *et al.*, 1971), one must use ascending concentrations within an olfactory threshold test. Pangborn R. M. *et al.* (1964) tested detection threshold for 2-heptanone three times, once in an ascending concentration order, once in a descending concentration order, and once in random order. Detection thresholds were lowest when tested with ascending concentrations and highest when tested with descending concentrations. A second step is to employ a sufficiently long ISI so as to minimize adaptation effects by allowing full recovery. Although most all published determinations of detection threshold employ ISIs in the range of 30–45 s, Koster E. P. (1971) reports that even ISIs of as long as 120 s do not allow for complete recovery at near-threshold levels. Effects on olfactory detection threshold can also result from the inverse of olfactory adaptation, namely olfactory facilitation. Facilitation consists of lower detection thresholds for one odorant after exposure to another (Engen, T. and Bosack, T. N., 1969). Interestingly, a determining factor on whether or not one odorant will facilitate the detection of another appears to be odorant solubility in water. When a significantly less soluble odorant is presented first, it facilitates the detectability of an ensuing more soluble odorant. By contrast, when a more soluble odorant is presented first, it reduces the detectability of an ensuing less soluble odorant, a phenomenon termed cross-adaptation. For example, using the long- and short-chain homologous alcohols C_3 (high solubility), C_4 (high solubility), and C_7 (low solubility), Corbit T. E. and Engen T. (1971) found that using C_7 as the adapting stimulus facilitated detection of C_3 and C_4, whereas using C_4 as the adapting stimulus inhibited detection of C_3. They hypothesized that these effects reflected the relative rates at which the odorants could cross the olfactory mucosa in order to then bind to receptors. Specifically, they argued that the low-solubility odorant changed the mucosal environment such that the higher-solubility odorants could then cross the mucosa more rapidly.

4.45.2.7 Reported Absolute Thresholds

Considering the above described sources of variance, namely method of odorant delivery, sniffing behavior, statistical analysis, nonolfactory effects, and

odorant order effects (adaptation and/or facilitation), it is not surprising that reports on absolute detection thresholds varied so widely across laboratories (Amoore, J. E. and Hautala, E., 1983). However, even data collected within laboratories initially suggested unusually high populational variance in olfactory detection thresholds. For example, detection threshold spans of as much as 5 (Brown, K. S. *et al.*, 1968) and 16 (Yoshida, M., 1984) log units within a homogeneous young and healthy population have been reported. Furthermore, the magnitude of this populational variance appears odorant dependent, significantly greater for some odorants than for others (Punter, P. H., 1983). In a critical study, Stevens and colleagues suggested that much of this variation may be explained by individual variation over time (Stevens, J. C. *et al.*, 1988). They tested three subjects on detection of three odorants over a period of 30 days. Every test consisted of an ascending staircase 2AFC paradigm, with five consecutive correct as criteria (plus an additional five correct for the next higher concentration). They found that the variability of each subject over time was similar to that seen in large groups at one point in time. In other words, they suggested that the dynamic properties of individual olfactory detection thresholds may underlie much of the apparent populational variance. However, when they pooled all their data for each of the three subjects, they found that the subjects were nearly identical. Taken together, these results suggest that the across-test variability reflected the poor power of the single test. Had the single test consisted of the 150 trials that contributed to each point in the pooled data, subjects' performance may have appeared stable. With this issue in mind, Walker J. C. *et al.* (2003) conducted repeated threshold testing using a 75 trial yes/no paradigm that took about 2.3 h to complete. Using such strict criteria, they failed to replicate the variability reported by Stevens J. C. *et al.* and concluded that thresholds are stable when meticulously determined. As concluded in this respect by Cain W. S. and Gent J. F. (1991), there is "little solace to those who may wish to measure quick and dirty olfactory thresholds".

In contrast to all of the above unintended sources of variance, olfactory thresholds are also influenced by various known factors. Principal amongst these is age. Olfactory detection thresholds are typically elevated two- to 15-fold in the healthy elderly in comparison with young adults (Schiffman, S. 1979; Cain, W. S. and Stevens, J. C. 1989; Doty, R. L. *et al.*, 1989; Cain, W. S. and Gent, J. F., 1991; Serby, M. *et al.*, 1991). This reduction in sensitivity is in fact clearly apparent by middle age (Cain, W. S. and Gent, J. F., 1991). In addition to age, detection thresholds are increased by exposure to environmental toxins, diseases that insult the peripheral components of the olfactory system (e.g., rhinitis), developmental diseases that insult the olfactory bulb (e.g., Kalmans), neurodegenerative diseases that may insult both peripheral and central components of the olfactory system (e.g., Parkinson's disease and Alzheimer's disease), and self-injurious behaviors such as excessive smoking or drinking of alcohol. Although reports of gender differences in olfactory detection thresholds have been mixed, a preponderance of evidence points to lower thresholds in women. Early studies by Bailey and colleagues suggested lower thresholds in men than in women (Bailey, E. H. S. and Nichols, E. L., 1884; Bailey, E. H. S. and Powell, L. M., 1885); however, later studies by Toulouse E. and Vaschide N. (1899) suggested the opposite. Still other studies found no difference between men and women in olfactory detection thresholds (Mesolella, V., 1934; Kloek, J., 1961; Matzker, J., 1965; Amoore, J. E. and Venstrom, D., 1966; Venstrom, D. and Amoore, J. E., 1968; Griffiths, N. M. and Patterson, R. L., 1970; Koelega, H. S. 1970;Koelega, H. S. and Koster, E. P., 1974; Dorries, K. M. *et al.*, 1989; Zatorre, R. J. and Jones-Gotman, M. 1990; Stevens, D. A. and O'Connell, R. J., 1991; Segal, N. *et al.*, 1995). In efforts to account for this variability, it has been suggested that a sex difference may be limited to specific odorants (Koelega, H. S. and Koster, E. P., 1974), or apparent only at particular points along the menstrual cycle. This too, however, has been a point of contention, with some studies suggesting lower (better) thresholds at time of ovulation (Le Magnen, J., 1952; Vierling, J. S. and Rock, J., 1967; Mair, R. G. *et al.*, 1978; Doty, R. L. *et al.*, 1981; 1982; Narita, S. *et al.*, 1992; Pause, B. M. *et al.*, 1996; 1999), others at the follicular phase (Henkin, R. I., 1974), others around menses (Koster, E. P., 1968; Doty R. L., 1976), or at menstruation (Le Magnen, J., 1952; Schneider, R. A. and Wolf, S., 1955; Good, P. R. *et al.*, 1976; Mair, R. G. *et al.*, 1978; Moriyama, M. and Kurahashi, T., 2000). Still other studies failed to find any differences across the menstrual cycle in olfactory detection thresholds (Amoore, J. E. *et al.*, 1975b; Herberhold, C. *et al.*, 1982; Filsinger, E. E. and Monte, W. C., 1986; Hummel, T. *et al.*, 1991; Kanamura, S. and Takashima, Y., 1991). Similarly, early pregnancy, which influences various aspects of olfactory perception, does not influence olfactory

detection threshold (Kolble, N. *et al.*, 2001). Whereas the bulk of the literature taken together may only imply lower thresholds in women, one recent study may have finally decided this issue. Dalton P. and colleagues (2002) measured detection threshold for benzaldehyde every 2 days, for 60 days. They found that whereas men's detection thresholds maintained a constant mean, women's thresholds decreased dramatically with time (Figure 4, middle panel). They both replicated this finding with an additional odorant (citralva) and demonstrated that it does not generalize to taste thresholds. In other words, whereas men and women had equal detection thresholds at baseline, they did not after training. This convincing study suggests that given the undertrained state of olfaction in most humans, differences between men and women are obscured (as reflected in the bulk of the literature). But once the full potential of the olfactory system is realized through training, women significantly outperform men in olfactory detection thresholds.

Training the olfactory system can serve not only to reduce detection threshold values from one concentration to a lower one, but can in fact also serve to enable detection of a previously completely undetectable odorant. The term specific anosmia is used to describe a state wherein a person with otherwise healthy olfaction is completely unable to detect a particular odorant, at any concentration. Although specific anosmia has been described for several odorants (Amoore, J. E., 1967; Amoore, J. E. *et al.*, 1975a; Amoore, J. E., 1977a; 1977b), it has been primarily studied with the odorant androstenone. Estimates of populational prevalence for androstenone anosmia range from ~2% to ~30% (review in Bremner, E. A. *et al.*, 2003). Considering that androstenone anosmia has a genetic component (Beets, M. G. J. and Theimer, E. T., 1970; Polak, E. H., 1973; Amoore, J. E., 1977a; 1977b), it has been considered as a possible psychophysical tool for probing the relationship between genetic makeup and specific olfactory abilities. One of the chief researchers of this phenomenon is Charles Wysocki. Wysocki, himself a nondetector of androstenone, noticed that after months of research and exposure, he had developed the ability to detect androstenone. In an effort to further explore this serendipitous observation, Wyscoki and colleagues systematically exposed androstenone nondetectors to androstenone (Wysocki, C. J. *et al.*, 1989). They found that repeated exposure induced detectability, which by 6 weeks of exposure was

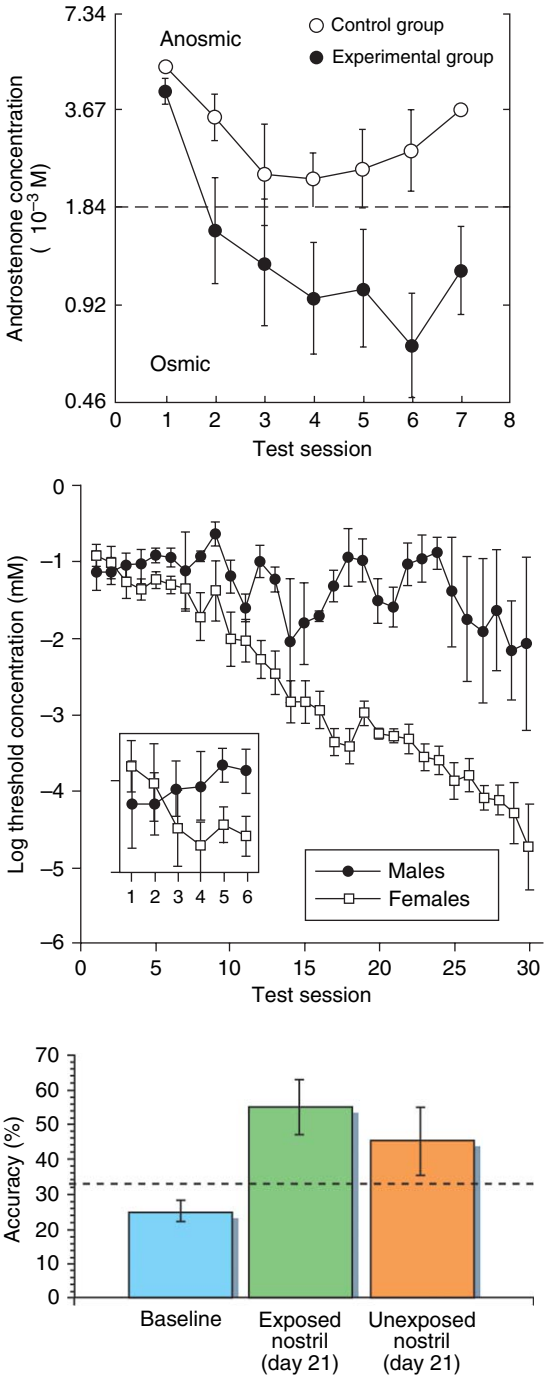

Figure 4 Improving olfactory detection threshold. The top panel depicts reductions in detection thresholds for androstenone during 6 weeks of exposure (Wysocki, C. J. *et al.*, 1989). The middle panel depicts reductions in detection threshold for benzaldehyde induced by 60 days of exposure in women but not men (Dalton, P. *et al.*, 2002). The bottom panel depicts detection of androstenone in the nostril that was exposed to androstenone vs. the unexposed nostril, following 21 days of exposure (Mainland, J. D. *et al.*, 2002).

significantly better than chance, and dramatically different from baseline (Figure 4, top panel).

What mechanisms underlie the plasticity evident in this and other studies where olfactory detection improved through practice? Was the improved performance the result of events in the nose or events in the brain? This question was addressed in experiments on rodents and humans. Yee K. K. and Wysocki C. J. (2001) surgically disconnected the epithelium from bulb in androstenone-anosmic mice. They then systematically exposed the now disconnected epithelium to androstenone over 10 days. When the epithelium-to-bulb connection regenerated 45–50 days later, they tested the mice for androstenone detection. Androstenone detection had improved significantly, leading the authors to suggest that plasticity underlying acquired olfactory abilities was peripheral, in the epithelium. Mainland J. D. *et al.* (2002) addressed the same question in humans. They repeatedly exposed only one nostril of androstenone nondetectors to androstenone, and then tested the unexposed nostril for detection. Following exposure, both the exposed and the naïve nostrils could detect androstenone, effectively doubling their detection accuracy (Figure 4, bottom panel). Since the two olfactory epithelia are not neurally connected at the peripheral level, Mainland J. D. *et al.* concluded that learning occurred via a central brain mechanism, such as olfactory bulb or cortex, which shared information from both nostrils. In contrast, Wang L. *et al.* (2004) conducted a study that led them to the opposite conclusion. These authors repeatedly measured olfactory evoked potentials (EOG) from the epithelium in the nose and olfactory event-related potentials (OERP) from the scalp concomitantly with an androstenone exposure paradigm. They found that increased androstenone detection was associated with changes in both the EOG and OERP. They concluded that a modified EOG necessarily implies plasticity and change at the level of the epithelium. A conclusion consistent with all the data is that exposure may induce changes at both the peripheral and central levels. Repeated exposure may indeed lead to increased expression of receptors at the epithelial level (Yee, K. K. and Wysocki, C. J., 2001), as well as to an increased ability of the brain to make sense of what was a previously senseless message (Mainland, J. D. *et al.*, 2002).

With all the confusion and disagreement regarding human olfactory detection thresholds, there is one fact that can be stated without controversy: human olfactory detection thresholds are exceedingly low, or in other words, the human olfactory system is a first-rate chemical detector. For example, the odorant ethyl mercaptan that is often added as a warning sign to propane can be detected at concentrations far below 1 part per billion (ppb), typically as low as 0.2 ppb (Whisman, M. *et al.*, 1978). This is equivalent to approximately three drops of odorant within an Olympic-size swimming pool – given two pools, a human could detect which pool contained the three drops of odorant! Finally, a report by the Japan Sanitation Center (Nagata, Y. and Takeuchi, N., 1990) suggests humans can detect isoamyl mercaptan at 0.77 parts per trillion (ppt)! This, to our knowledge, is the lowest reported human detection threshold (Figure 5).

How does this sensitivity compare with other mammals? The few direct within-experiment comparisons of olfaction in humans and other species have focused on tasks other than absolute detection threshold (Slotnick, B. M. and Ptak, J. E., 1977). Matthias Laska and colleagues have amassed detection thresholds across several species and have compared their data to that obtained by others from humans. In one such study, they measured detection threshold for the fox anal gland odorant 2,4,5-trimethylthiazoline (TMT) in rats, squirrel monkeys, and spider monkeys (Laska, M. *et al.*, 2005a). They found that whereas monkeys had thresholds comparable to those of previously found in humans (in the single ppb range) (Figure 6), rats detected TMT in

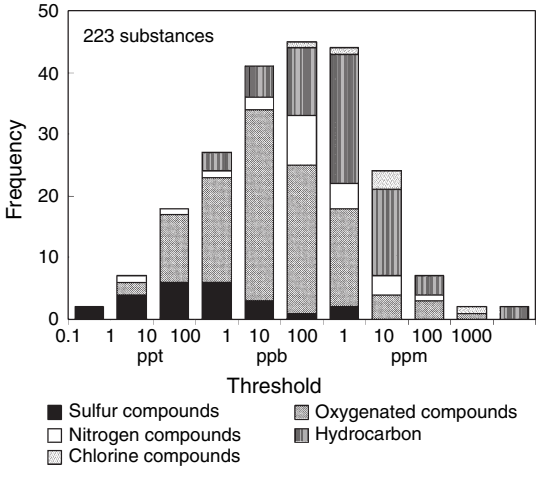

Figure 5 Human detection thresholds. Distribution of detection thresholds for different types of odorants. Humans can detect compounds containing sulfur in the ppt range (Nagata, Y. and Takeuchi, N., 1990).

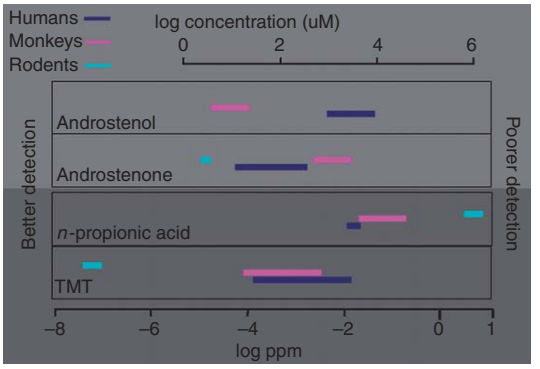

Figure 6 Detection thresholds across species. The data are amassed from studies by Laska and colleagues and are for detection of the fox odor 2,4,5-trimethylthiazoline (TMT), *n*-propionic acid, and the two steroidal compounds androstenol and androstenone. The two shades of gray distinguish the units in which results were reported, dark gray in log concentration of the vapor, and light gray in log concentration of the odorant liquid. The extent of the lines reflects the reported variance across studies. The important point illustrated is that each species excels at detecting particular odorants. For example, humans outperform rats and monkeys at detecting *n*-propionic acid. That said, one must keep in mind the limitation of comparing across studies that used different methods of delivery and statistical criteria.

the subpart per trillion (ppt) range (between 0.04 and 0.1 ppt). This is the lowest olfactory detection threshold ever reported for any animal.

This dramatic difference between rats on one hand and primates (including humans) and monkeys on the other seemingly supports the qualitative distinction considering rats and dogs as macrosmatic and primates and monkeys as microsmatic. However, Laska has suggested that this distinction may have been significantly influenced by the behavioral relevance of the odorants tested. Squirrel monkeys and pigtail macaques are better than rats at detecting a host of odorants that are not behaviorally significant to rats. For example, both squirrel monkeys and pigtail macaques outperformed rats by at least an order of magnitude at detecting *n*-propionic acid and *n*-pentanoic acid (Laska, M. *et al.*, 2004). Thus, one would like to see a comparison of detection thresholds for an odorant that is behaviorally significant to humans. Unlike the case of rats and TMT, however, humans are not faced with ongoing olfactory detection of predators, other than other humans. Indeed, although not in a predatory context, a host of steroidal compounds have been implicated in olfactory communication between humans (Monti-Bloch, L. *et al.*, 1998; Jacob, S. *et al.*, 2002; Bensafi, M. *et al.*, 2003a; 2004a; 2004b). Laska and colleagues measured detection thresholds for such compounds in monkeys (Laska, M. *et al.*, 2005b). In comparing their results to those obtained by others, they concluded that androstenone is best detected by mice, less so by monkeys, and even less by humans and pigs. In contrast, androstenol is better detected by humans than by monkeys (no data for mice and pigs). Summing up the efforts of Laska and colleagues, rodents outperform monkeys for some odorants, but monkeys outperform rodents for others. Similarly, monkeys outperform humans for some odorants, but humans outperform monkeys for others – these results are illustrated in Figure 6. Thus, any cross-species comparison of olfactory detection threshold must consider the behavioral relevance of the odorants tested. Furthermore, it is noteworthy that reported detection thresholds in nonhuman animals were obtained after hundreds, sometimes thousands of training trials. By contrast, most human thresholds were obtained after minimal training, if any. Considering the previously noted malleability of olfactory detection, it is tempting to consider the possibility that extensive training may induce/reveal detection thresholds in humans that rival those of macrosmatic mammals.

4.45.3 Olfactory Discrimination

One step up from olfactory detection in the hierarchy of olfaction is olfactory discrimination. Discrimination can be between two concentrations of the same odorant, or between two different odorants, at either the same or different concentrations. In order to discriminate between two odorants (smelled in succession), one must be able to detect them, form a neural representation of the first, and maintain this representation in short-term memory (Wilson, D. A. and Stevenson, R. J. 2003a; 2003b). The nature of this representation, however, is more akin to a sensory memory (Cowan, N., 1995) than a semantic or linguistically mediated memory, and discrimination is generally understood to occur without accessing long-term memory associations with the odorants, or semantic representations of the odorant, processes more properly associated with olfactory identification. The study of olfactory discrimination is susceptible to all the unwanted sources of variance described for the study of detection, namely methods of odorant delivery, sniffing behavior, statistical deduction, and experimental arrangement.

4.45.3.1 Discriminating between Different Concentrations

The simplest case of olfactory discrimination is that between two concentrations of the same odorant. Closely linked to the question of the minimal difference in concentration that can be discriminated is the nature of the relationship between odorant concentration and perception. In general, as the concentration of an odorant increases so does its perceived intensity (it is noteworthy that in some odorants, shifts in concentration are accompanied by shifts in odor quality as well) (Gross-Isseroff, R. and Lancet, D., 1988). The function that relates stimulus magnitude (concentration) to perceived magnitude (intensity) is a kind of psychometric function that can be measured. In this section, we will first describe how this psychometric function is estimated, and then describe how it is related to the issue of intensity discrimination.

The basic method for relating stimulus to perceived magnitude is referred to as magnitude estimation. Typically, many subjects are presented with many trials of an odorant stimulus, each trial at a different concentration. Subjects are asked to rate the intensity of each trial on a linear scale. Rating intensity can be achieved by assigning a number to the stimulus on a Likert scale (typically between 1 for low intensity and 9 for high intensity), or alternatively, by marking a line on a visual-analog scale (VAS). A VAS consists of a horizontal line presented on either paper or monitor, which is also accompanied by verbal descriptors at two or more points along the line. A typical VAS for intensity estimations may have the descriptor "barely detectable" at one end, and "the strongest smell I have ever experienced" at the other. On every trial, subjects cross the line at any location between these two extremes in a manner that reflects their perception. Using number assignment, Stevens S. S. (1957) and others found that the function which best describes the relation of odor concentration to perceived intensity was a simple power function defined as:

$$R = kS^b$$

Where R is perceived intensity, S is stimulus concentration, k is a constant for the logarithmic intercept, and b is a constant for the logarithmic slope. In logarithmic terms, the function is:

$$\mathrm{Log}R = b(\mathrm{Log}S) + \mathrm{Log}k$$

Figure 7 contains typical data from such an experiment. Power functions describe the relationship between perceived magnitude and stimulus magnitude in all sensory modalities including olfaction, and in all cases the slope is less than 1, so that successive increases in stimulus magnitude produce successively smaller and smaller increases in perceived magnitude. One implication of this saturating or compressed response is that doubling of stimulus magnitude will produce less than a doubling in its perceived intensity. Furthermore, the degree of this compression (i.e., the slope parameter) appears to be odorant specific. Cain W. S. (1969) demonstrated that this compression reflected an odorant's solubility in water. As odorant solubility increased, the degree of compression decreased. This, like the previously described effect on facilitation, may be the result of the higher rate at which more soluble odorants can cross the olfactory mucosa in order to bind to olfactory receptors (Mozell, M. M. and Jagodowicz, M., 1973). This predictable link between an odorant's solubility and the slope of it is power function forms, in our view, one of the most successful implementations of olfactory psychophysics in that is fulfils the previously mentioned goal of defining rules that link the physical stimulus to the resultant percept.

With an understanding of how odorant concentration is related to perceived intensity, we turn to the question of how discriminable different concentrations are from one another. The minimal perceptible change

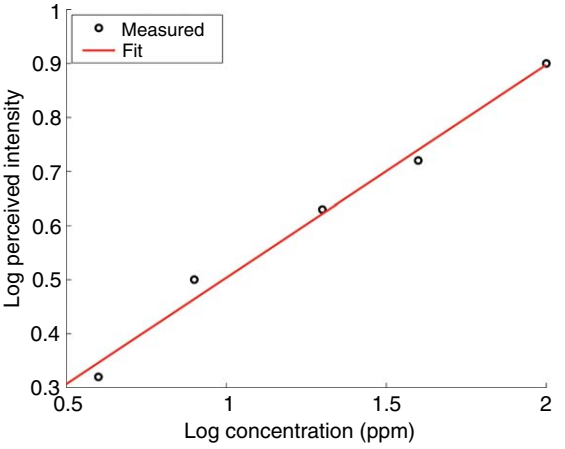

Figure 7 The relationship between odorant concentration and perceived intensity. As odorant concentration increases, so does perceived intensity. When expressing concentration and perception in log units, the relationship can be described by a power function, with a slope that is typically <1.

in stimulus magnitude is known as the just noticeable difference (JND) and follows the law of JND, which states that the minimum increase in a stimulus required for a subject to take notice (symbolized as ΔS) is in constant proportion to the initial stimulus (Fechner, G. T. 1860). This proportion, called the Weber fraction:

$$\Delta S = kS$$

where ΔS is the increment in S (JND), S is the standard stimulus, and k is Weber's fraction, is measured empirically by the method of constant stimuli. This equation implies the Weber–Fechner law:

$$R = k\log(S/S_a)$$

where R is the perceived magnitude and S_a is the absolute threshold for detection of the stimulus. Of course, this law applies only to detectable or suprathreshold stimuli.

In a typical JND experiment, a subject performs many trials in which they smell in rapid succession first a standard and then a comparison stimulus. Different comparison stimuli are used, some equal to the standard, and others differing by fixed proportions. The subject rates the two stimuli as either same or different. Typical Weber fractions for human vision and audition are in the 10% range (Mueller, C. G., 1951). In other words, reliable discrimination is achieved for a 10% increment from the standard. Initial experiments using the method of constant stimuli in olfaction suggested that olfaction indeed follows Weber's law, but that it is characterized by relatively high Weber fractions of between 25% and 33% (Gamble, R. C. 1899). This value was not only significantly higher than human auditory and visual Weber fractions, but also orders of magnitude higher than olfactory Weber fractions obtained in macrosmatic mammals. Slotnick B. M. and Ptak J. E. (1977) used a modified AML procedure to determine Weber fractions for the odorant amyl acetate in rats and humans within the same study. Similar to previous reports, they found human Weber fractions of ~30%, but rat Weber fractions of ~4%. However, in a landmark study, Cain W. S. (1977) found that the high Weber fractions reported for humans may have reflected fluctuations in the stimulus. Once the stimulus was carefully controlled, Cain revealed human olfactory Weber fractions of as low as 7% for some odorants (*n*-butyl alcohol), thus grouping olfaction together with vision and audition in its relative sensitivity, and reducing the implied magnitude of difference between humans and macrosmatic mammals in this respect.

4.45.3.2 Discriminating between Different Odorants

In the preceding section, the discriminability of two kinds of odor was parameterized in terms of the only difference between them, namely the concentration of the odorant. Concentration is a numerical scale, which permits us to define a metric on the difference in stimuli, and then relate the difference in perception to this stimulus difference. In comparing the discriminability of different odorants, that is, different species of molecules, there is no obvious metric that defines the extent of differences between them. For example, how different is methane from ammonia? How can we define this as a number? The question of how to define a metric of stimulus similarity against which to gauge discriminability is crucial to understanding olfactory discrimination. A variety of studies have used a variety of different chemical properties of odorants to define metrics of similarity to see how they affect discriminability. The ways in which molecules can change, however, number in the hundreds, and a systematic study of all of them with respect to discriminability, is close to impossible.

Beyond the essential question of how to define stimulus similarity, there are further issues involved in how to quantify discrimination. Discrimination between different odorants can be considered as an absolute binary decision, in which case it can be probed using 2AFC with same or different as answers, or three-alternative forced-choice (3AFC) where subjects select the odorant that is different from the two others (more than two others can also be used). Matthias Laska and colleagues have used such 3AFC paradigms to test discriminability of odorant molecules as a function of various aspects of their physical structure. They found that the greater the difference in carbon chain length between any two odorants, the easier they were to discriminate (Laska, M. and Freyer, D., 1997). Furthermore, they found that humans can discriminate aliphatic odorants equal in number of carbons, but different in oxygen moiety (Laska, M. *et al.*, 2000), and differences in structures that share a benzene ring rather than a linear and unbranched carbon chain (Laska, M., 2002). Laska and colleagues argued that such discrimination data can be used as a tool to probe the dimensionality of odor quality. Specifically, they assume that easier discrimination reflects greater perceptual difference. Thus, because discrimination

became easier as the difference in carbon chain length increased, they conclude that carbon chain length reflects a dimension of olfactory perception. Unfortunately, it is generally impossible to vary only a single parameter of variance across a molecule. For example, increasing odorant carbon chain length will decrease odorant solubility, which leads to a diminution in perceived intensity (Cain, W. S., 1969). Thus, when subjects are able to discriminate odorants of different carbon chain length, it is impossible to say whether the ability is due to differences in intensity, solubility, some other attribute, or chain length *per se*.

One class of molecular changes that avoids most of these confounding problems is that of enantiomeric pairs. Enantiomers are mirror-image or chiral molecular structures that under most circumstances will not differ in solubility or many other chemical properties. Humans can discriminate many enantiomers by smell (Jones, F. N. and Velasquez, V., 1974; Jones, F. N. and Elliot, D., 1975). However, some enantiomeric pairs are not easily discriminated (Theimer, E. T. *et al*., 1977; Laska, M. and Teubner, P. 1999), and still others are easily discriminated whereby one has a distinct odor and the other has no clear olfactory percept at all (Laska, M. and Teubner, P., 1999). Although these experiments reduce the potential sources of variance underlying discrimination, they still fail to link a particular molecular aspect of odorants to a particular olfactory percept or quality.

The overwhelming impression following review of the human olfactory discrimination literature is that humans can discriminate nearly any molecular change in odorant structure. An alternative strategy to probing the olfactory system through discrimination studies is to focus not on the incredible achievements of olfactory discrimination, but rather on those rare instances where the olfactory system fails to discriminate changes in odorant structure. Keller A. and Vosshall L. B. (2004) used discrimination studies to probe what has been termed the vibrational theory of olfaction. Specifically, the most widely accepted theory of olfaction holds that the molecular structure, or shape, of an odorant is the determining factor in its interaction with a receptor and hence in creating a percept. According to this theory, different receptors bind to particular structural elements of the odorant molecule, termed odotopes, creating a combinatorial pattern of neural activity across receptors that is the basis for the odor percept. A controversial alternative theory of olfaction suggests that olfactory receptors act as biological spectroscopes, encoding the vibrational spectrum of odorant molecules (Turin, L. 1996; 2002). Whereas the vibrational theory predicts that the shape of a molecule does not determine its percept, the simplest version of odotope theory predicts that the vibrational spectrum of a molecule does not determine its percept. These different predictions suggest a simple test of the two theories, namely locating a pair of molecules that are isoteric (same shape), yet whose vibrational spectra differ. The necessary pair of molecules can be made by isotope substitution; for example, substituting deuterium for hydrogen in one version of a molecule will change its vibrational spectrum but leave its shape unchanged. A simple version of odotope theory predicts these two molecules will smell the same, while the vibrational theory predicts they will smell different. In support of the vibrational theory, Luca Turin suggested that deuterated and undeuterated acetophenone smell quite different (Turin, L. 1996; 2002). To further address this, Keller and Vosshall systematically tested discriminability of these two odorants using several methods. They used a number-based similarity scale, and two variants of 3AFC, a triangle-test where subjects were asked to identify the one odorant jar of three that was different (two were indeed the same, either deuterated or undeuterated), and a duo-trio test where two stimuli were presented, and subjects were asked to match one to a third reference. Overall, subjects were unable to discriminate deuterated from undeuterated acetophenone, and Keller and Vosshall concluded that they found no psychophysical support for the vibrational theory.

Given the difficulties of determining how the myriad possible factors that vary across molecules might change perceptual qualities, that is, the difficulties in determining a similarity metric in the stimulus space, one possible strategy is to directly probe the similarity metric in the perceptual space. This is typically done by presenting pairs of stimuli and asking subjects to rate their similarity on a Likert scale or VAS (e.g., the question "how similar are these two odors?", with a line ranging from "not at all" to "identical"). A shortcoming of such scales is that they typical asymptote at both floor and ceiling, making them relatively insensitive for odors that are very similar or dissimilar. This limitation can in part be addressed using

performance-based measures of similarity scaling (Wise, P. *et al.*, 2000). For example, in both vision and audition, more difficult discriminations, namely discriminations between more similar stimuli, take longer. Thus, one can measure time-to-discrimination between various olfactory stimuli and assume that stimuli that take longer to discriminate are more similar in terms of olfactory quality (Wise, P. M. and Cain, W. S., 2000).

4.45.3.3 Speed of Olfactory Discrimination

Olfaction is not typically thought of as a rapid process. Indeed, when faced with olfactory discriminations, humans will typically take several sniffs, a sniffing bout, before they settle upon their discrimination judgment. Laing D. G. (1983) compared performance obtained in such natural sniffing bouts to that obtained in a single sniff. He found that for olfactory detection and intensity discrimination, one sniff produced results as good as those from a sniffing bout. In fact, a sniff as short as 400 ms was sufficient for maximal intensity discrimination accuracy. In a second study (Laing, D. G. 1986), subjects were trained to limit sniff duration to the sound of a buzzer. Sniffs lasting 420 ms were sufficient for 90% discrimination accuracy across different odorants. However, when odorant concentration was lowered to near-threshold, there was a time-accuracy trade-off in that shorter sniffs impaired discrimination accuracy. Whereas this experiment by Laing emphasized speed over accuracy, Wise and Cain emphasized accuracy over speed (Wise, P. M. and Cain, W. S., 2000). They compared discrimination times for perceptually similar (difficult comparison) and dissimilar (easy comparison) odorant pairs and found that latency decreased as accuracy increased. In other words, easy comparisons were made faster than difficult comparisons. These seemingly contradictory results (Figure 8) are simply two sides of the same coin, namely the speed-accuracy trade-off, which is affected by bias. If subjects are instructed to be fast, high speed will reflect inaccuracy. If subjects are instructed to be accurate, high speed will reflect accuracy. These contingencies are easily controlled in human experiments through appropriate instructions, but can be a cause for confusion in interpreting animal experiments (see Uchida, N. and Mainen, Z. F., 2003 vs. Abraham, M. H. *et al.*, 2004, compared in Khan, R. M. and Sobel, N., 2004).

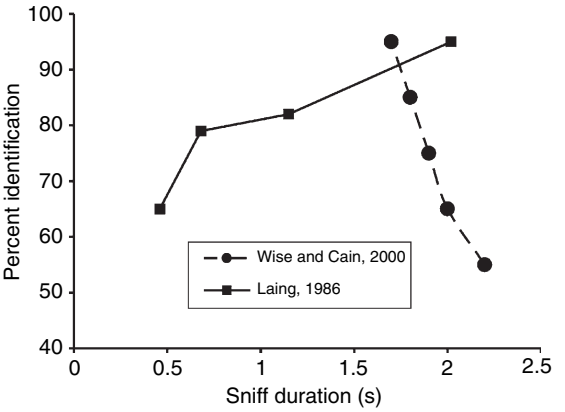

Figure 8 Time-accuracy trade-off. Behavior is modified by bias. Thus, when Laing D. G. (1986) stressed speed, the more subjects rushed, the less correct discriminations they made. In contrast, Wise and Cain stressed accuracy. Thus, when discriminations were easy and subjects were very confident, they answered at once. When discriminations were difficult, they took their time.

Finally, Johnson B. N. *et al.* (2003) used measurements of sniffing as an indirect performance-based measure to assess the latency-to-discrimination of differences in odorant intensity. Specifically, sniff vigor (flow rate, volume, and duration) is inversely proportional to odorant concentration (Laing, D. G. 1983; Warren, D. W. *et al.*, 1994; Sobel, N. *et al.*, 2001; Walker, J. C. *et al.*, 2001). Higher intensity odorants are sampled with reduced vigor, and lower intensity odorants are sampled with increased vigor. Johnson *et al.*, used careful recordings of sniff airflow combined with tight temporal control over odorant delivery. They found that sniffs start off with an extremely stereotyped structure, but are then modulated in accordance with odorant concentration by as early as 160 ms following sniff onset for an odorant that may have a trigeminal component, and 240 ms for a pure olfactant (Figure 9). These values are the lowest we are aware of for olfactory discrimination in humans and suggest that contrary to the common notion, olfaction is fast. Here a nonverbal measure of discrimination suggested that the olfactory system discriminated between two stimuli in less than 200 ms. Considering that odorant transduction alone is expected to account for at least ~150 ms of this latency (Firestein, S. *et al.*, 1990), this result suggests that the cognitive process of olfactory discrimination was extremely rapid.

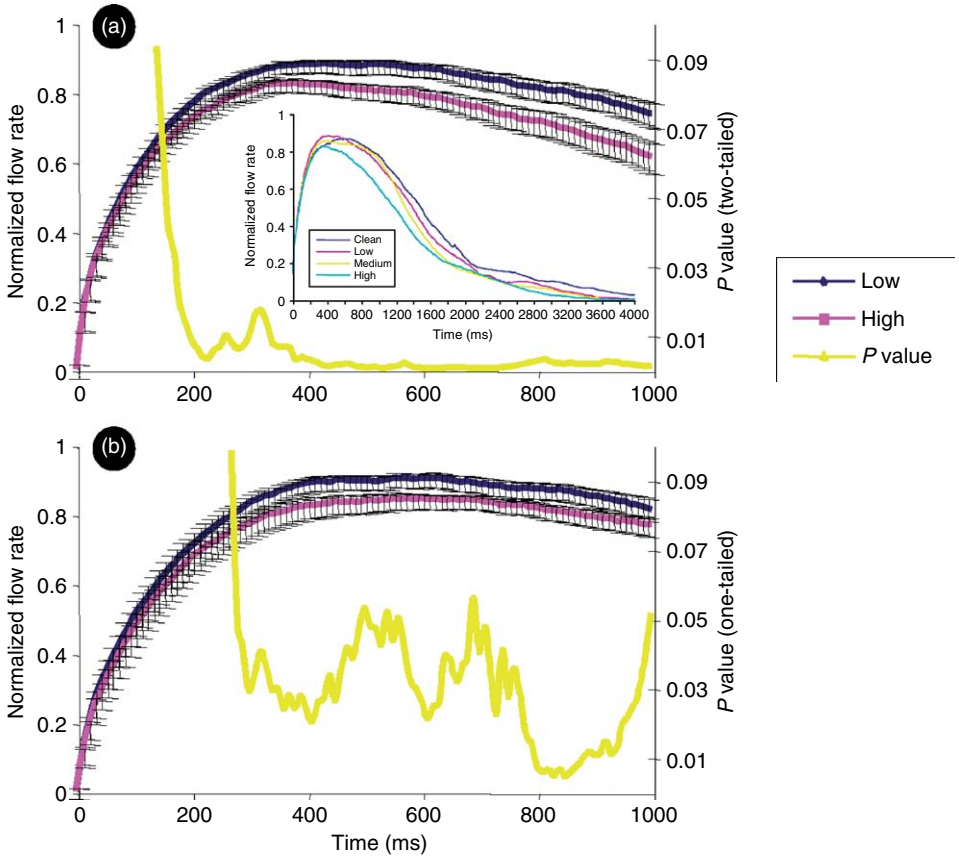

Figure 9 Speed of olfactory discrimination. Sniff magnitude serves as a nonverbal performance-based measure of discrimination. The inset depicts the full mean sniff of 28 subjects sniffing clean air, or one of three intensities of odor. Sniffs clearly separate as a function of odorant concentration. To probe the point of separation, only the first second of the sniff of 28 subjects for high and low concentration of propionic acid (a) and phenyl ethyl alcohol (PEA) (b) are depicted. The yellow line reflects a *t*-test between both traces. Sniff velocity drops when sniffing high as compared with low-concentration propionic acid by 160 ms after sniff onset and 240 ms for PEA.

4.45.4 Olfactory Identification

One step up from olfactory discrimination in the hierarchy of olfaction is olfactory identification. Whereas discrimination calls upon working memory to enable comparison of one odor with another, identification calls upon long-term memory in that in its explicit form, it consists of linking an odorant with a previously stored semantic representation. The study of olfactory identification is methodologically simpler than the study of detection and discrimination because the process of interest is slower and is mostly irrelevant at near-threshold concentrations. Despite this simpler methodological setting, olfactory identification remains the least understood perceptual process in olfaction. A basic goal of the study of olfactory psychophysics is a characterization of the structure of the perceptual space and its relation to the structure of the stimulus space. In vision, the laws of optics and the nature of light provide powerful constraints on the perceptual space: spatial location in the world is mapped onto spatial location in the retina which is subsequently preserved in subcortical and cortical processing, photon density maps onto brightness, and photon wavelength maps onto perceived color. Similarly in audition, characteristics of vibrations in the air can be mapped onto perceived qualities such as loudness, frequency, timbre, and so on. In olfaction, although there is agreement about the basic stimulus, namely relatively small molecules, there is surprisingly little consensus as to which aspects of the stimulus are connected with which aspects of perceptual experience. Indeed, there is not a perfumist or scientist who could predict the smell of a novel chemical structure, nor the chemical structure of a novel smell. This is unequivocally the

major question in the field of olfaction in general and olfactory perception in particular. Regarding this lacuna, Amoore, J. E. asked in 1970 "[h]ow can something *right in front of your nose* still remain a mystery while men are flying to the moon?" (Amoore, J. E., 1970). Now 35 years later, rovers are exploring mars, yet this question remains unanswered.

4.45.4.1 Language and Olfactory Identification

Free identification of odors is a surprisingly difficult task. Unprompted (without the use of multiple choices) odor identification accuracy of generally familiar odors is around 50% (Sumner, D., 1962; Lawless, H. T. and Engen, T., 1977; Cain, W. S., 1979; Engen, T., 1987; de Wijk, R. A. and Cain, W. S., 1994), although it can exceed 85% in experts (Bensafi, M. *et al.*, 2002b). Although odor familiarity can increase identification scores (Homewood, J. and Stevens, R. J., 2001), and discrimination sores (Savic, I. and Berglund, H. 2000), it does not always enable unprompted identification. Often subjects will acknowledge that the odor is familiar, but will be unable to name it. This situation has been named the tip-of-the-nose phenomenon (Lawless, H. T. and Engen, T., 1977), analogous to the tip-of-the-tongue phenomenon in word recall (Brown, R. and McNeill, D., 1966). Richardson J. T. and Zucco G. M. (1989) suggested that this phenomenon may result from subjects' tendency to use a small, impoverished set of verbal labels to encode odor memories, rather than precise and differentiating labels. When trying to recall a label at re-exposure to an odorant, the odor may be recognized, but may not activate a sufficiently precise differentiating label, leading to recognition without identification. To probe this issue, Cain W. S. (1979) trained participants to identify odors before testing them. Teaching subjects labels for odors over five sessions improved identification performance from 60% to 94%. In view of these results, Schab F. R. (1991) suggested that odor identification consists of two components, a perceptual process of odor encoding, and a verbal-semantic process that consists of the activation of potential labels in semantic memory, and the selection of the most appropriate label from those activated. On this account, the poor unprompted identification performance commonly observed might be explained by a limitation in odor encoding, or in the verbal-semantic treatment, or both (Schab, F. R., 1991; de Wijk, R. A., Schab, F. R. and Cain, W. S., 1995). Evidence for such a dual-component system can be seen in the influence of verbal context on olfactory perception. If the same odorant is presented within a positive versus negative verbal context, such as natural versus artificial, it is perceived as more pleasant (Herz, R. S., 2003). The magnitude of this effect can be significant. For example, Herz R. S. and von Clef J. (2001) presented subjects with a mixture of isovaleric acid and butyric acid labeled as either parmesan cheese or vomit. Using a 9-point pleasantness scale (9 = most pleasant), the same odorant was rated at 5.06 in the former condition and 1.68 in the latter. This result suggests an interesting interaction whereby odor perception is a poor generator of verbal labels (poorer than in other senses), yet verbal labels are a viable modifier of odor percepts (seemingly more so than in other senses).

Although the tip-of-the-nose phenomenon intuitively suggests that poor naming of odorants reflects failures at the level of verbal-semantic processing rather than perceptual processing, some lines of evidence suggest otherwise. For example, odor naming ability is highly correlated with odor discrimination ability, despite the latter's independence of semantic processes (de Wijk, R. A. and Cain, W. S., 1994). Jonsson, F. U. *et al.* (2005) further argued that the tip-of-the-nose phenomenon may not be as prevalent as one might think. These authors dissociated the tip-of-the-nose phenomenon from what they called a feeling of knowing, a sense of general familiarity that they argue reflects poor perceptual encoding of the odor. They presented subjects with 30 common odorants and collected subjective assessments from subjects regarding their experience during attempted identification. These subjective assessments were classified as either reflecting tip-of-the-nose phenomenon or feeling of knowing. They found that in failed identification, 4% of trials were accompanied by strong tip-of-the-nose phenomenon and 24% were accompanied by a strong feeling of knowing. From this, the authors argued that poor perceptual encoding accounts for a greater proportion of failed odor naming than does poor verbal-semantic processing.

The universally poor ability to freely recall odor names has shaped standard tests of olfactory identification, which generally eschew free recall in favor of forced multiple choice (Doty, R. L. *et al.*, 1984a; 1984b; Cain, W. S. *et al.*, 1988; Kobal, G. *et al.*, 1996; Hummel, T. *et al.*, 1997; Nordin, S. *et al.*, 1998). The most widely used of these tests is the University of Pennsylvania smell identification test (UPSIT) (Doty, R. L. *et al.*, 1984a; 1984b). This test consists of 40 microencapsulated odorants that subjects have

to scratch and sniff. For each odorant, their task is to choose among four alternative labels the one that best describes each odor (e.g., for the smell of pizza, the labels gasoline, pizza, peanuts, and lilac are proposed). The UPSIT may have some shortcomings as a scientific tool in that it was designed with clinical testing in mind. That said, it remains the only real standard test in olfaction and has proved enormously valuable in characterizing olfactory identification in both health and disease. The UPSIT and similar tests have revealed that olfactory identification is generally better in women than in men (Doty, R. L. *et al.*, 1985), that odor identification performance declines with age, usually following an inverted U-curve, best in young-adults and poorest in children and old-adults (Doty *et al.*, 1984c; Doty, R. L., 1989), and that olfactory identification declines in many diseases, to the extent that it may be diagnostic for some.

4.45.4.2 Identification of an Odor Rather than Its Parts

The nose is commonly thought of as a kind of chemical analyzer. As reviewed elsewhere in this book, specific chemicals are identified by specific receptors in a lock-and-key-type interaction based on receptor configuration and chemical functional groups. Furthermore, these individual chemicals are then represented in specific spatial patterns of activity on the surface of the olfactory bulb. In other words, the olfactory system is studied as a type of analytical tool, such as a chromatograph, which parses and stores information such that subcomponents may be identified from the original stimulus. Some behavioral researchers, however, hold a different view of olfactory processing. They believe that olfaction functions as a synthetic rather than an analytic process (Livermore, A. and Laing, D. G., 1998a; 1998b; Wilson, D. A. and Stevenson, R. J. 2003a; 2003b). By this, they mean that the olfactory system does not reduce the input into recognizable subcomponents but rather that it is the amalgam input that is recognized as a whole. The main line of evidence for this view is from the so-called gestalt aspect of olfaction evidenced in the perception of odor mixtures.

At the simplest level, human subjects are poor at determining whether an odor is a pure odorant (that we will refer to here as a simple odorant) or odorant mixture (that we will refer to here as a complex odorant) (Moskowitz, H. R. and Barbe, C. D., 1977). Furthermore, extensive characterization of odor mixture perception by Laing and colleagues has repeatedly found that humans cannot correctly identify the individual constituents of a mixture containing more than four or five constituents. In one study (Laing, D. G. and Francis, G. W., 1989), subjects were initially familiarized with seven odorants and their common names. Subjects were then asked to identify which of these seven components were in mixtures presented by an air-dilution olfactometer. Identification accuracy decreased as the number of components in the mixture increased. Performance was only marginally better than chance for four components and at chance for five components (Figure 10). As the actual number of components in the mixtures increased, the number of estimated components increased as well, but lagged behind the true number. Such performance is unlikely to be the result of inadequate experience as expert perfumers revealed very similar results (Livermore, A. and Laing, D. G., 1996). However, component identification is better for familiar than unfamiliar odors (Rabin, M. D., 1988).

Subjects' ability to identify mixture components when constituents were themselves complex odorants was at the same level of performance as when constituents were simple odorants (Livermore, A. and Laing, D. G., 1998a; 1998b). This critical result suggests that odorants were represented as irreducible objects that used equal neural processing capacity, whether they were simple or complex. This irreducibility was further evidenced in that subjects are worse at distinguishing the components of complex odors they had been trained to identify as a single odor, yet when presented with only some of

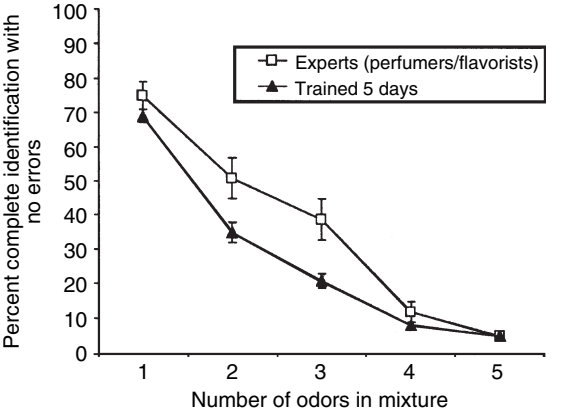

Figure 10 Odor mixture perception. Results from Laing and colleagues demonstrate that both expert perfumers and laypeople alike can identify up to four components of an odorant mixture.

the constituents of a learned odor object, they reported greater perception of qualities normally associated with the other constituents they had previously associated (Stevenson, R. J., 2001a; 2001b). This suggests that the mixed odorant is being represented as a single object, and when a portion of the object is presented the whole object is recalled.

These studies suggested that odorant qualities are blending together to decrease identification of components. To test this, Livermore A. and Laing D. G. (1998a; 1998b) tested mixture component identification using two sets of eight odorants chosen by a panel of expert perfumers as a set of bad blending odorants and a set of good blending odorants. As they predicted, component identification accuracy decreased with mixture complexity regardless of odorant group (good or bad blenders). Subjects were unable to identify more than three or four components in a mixture. However, subjects were significantly better at identifying components for the bad blending odorants than the good blending odorants.

Taken together, these experiments have been presented by some as evidence that olfaction is a synthetic rather than an analytic sense, which is to say that olfaction deals primarily with odor objects rather than odor molecules (Wilson, D. A. and Stevenson, R. J. 2003a; 2003b). It is clear, however, that olfaction, like all other senses, is both analytic and synthetic, and that these terms should be understood not as alternative construals but as descriptive of different levels of sensory processing. Consider an analogous situation in auditory processing. The sensory apparatus (the hair cells on the cochlea) is laid out to encode sound frequency in a linear fashion, and so the analytic basis set for audition is the set of pure tones within the audible range. As it is easy to generate pure tones (e.g., with tuning forks), we have the advantage of being able to probe the system with its analytic atoms. In olfaction, however, the basis set of the system is comprised of the few hundred different olfactory receptor types that are expressed in a particular organism. In general, each receptor responds to a range of molecules, and each molecule reacts with a number of receptors, so that individual molecular species are not the analytic atoms of the system. The set of atoms (or tuning forks) for olfaction would be a set of stimuli each of which reacted with only a single type of olfactory receptor. It is unlikely that many such olfactory stimuli exist. Continuing the comparison to audition, even an odorant composed of a single molecular type is thus analogous to a complex sound, not a pure tone. It is little surprise, on this view, that identification of complex and simple odors in mixtures is equal. Thus, to say that olfaction deals with olfactory objects rather than olfactory molecules is somewhat to have missed the point: molecules are not the analytic unit for olfaction but are themselves olfactory objects. Reverting to the analog in audition, if a viola is played simultaneously with a violin, a flute, a cello, and a trumpet, the ability of the system to distinguish the components (the particular instruments) from the mixture will be no better than the case of mixtures of molecules, and both may reflect fundamental information processing constraints.

Thus, in both audition and olfaction, the system begins with an analytic basis set, which must then be processed, in the light of much top-down information such as familiarity and learning the use of verbal labels, and attention to perceptual objects. The problem of mixture analysis in olfaction is akin to auditory scene analysis (Alain, C. and Arnott, S. R., 2000; Haykin, S. and Chen, Z., 2005) and should not be understood as a problem peculiar to olfaction. Inasmuch as the labels analytic and synthetic are useful, it is to remind us that olfaction, like all sensory modalities, is a complex, multilayered process.

4.45.4.3 Nostril-Specific Odor Tuning

Almost all odors that humans encounter in their environment are mixtures. Using mixture perception, Sobel N. *et al.* (1999) set out to ask whether the olfactory percept is equal across nostrils. Nostrils can be divided according to two criteria. One is the simple anatomical criterion, namely a left and right nostril. A second criterion is nasal airflow. In mammals, the rate of airflow is usually higher in one nostril than in the other. This occurs because a bilateral highly vascularized structure, the nasal turbinate, swells with blood flow in either one nostril or the other, increasing the resistance to airflow in one nostril in comparison to the other (Principato, J. J. and Ozenberger, J. M., 1970; Bojsen-Moller, F. and Fahrenkrug, J., 1971; Hasegawa, M. and Kern, E. B., 1977) (Figure 11(a)). The nostril with higher airflow, left or right, alternates on an ultradian rhythm of uncertain periodicity (Gilbert, A. N. and Rosenwasser, A. M., 1987; Mirza, N. et *al.*, 1997). Thus, nostrils can be designated either left and right or high flow (HF) and low flow (LF). However, in studies where one nostril was occluded in order to test the other, results regarding asymmetry in olfactory performance were mixed.

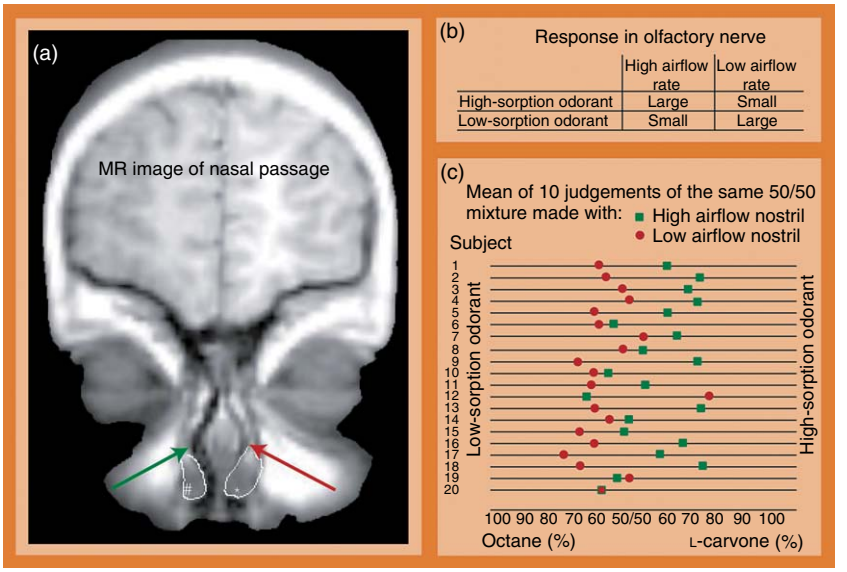

Figure 11 Nostril-specific odor tuning. (a) Magnetic resonance (MR) image of the nasal passage, which appears dark. The swollen (*) and relaxed (#) turbinates, outlined in white, result in an occluded right nostril (red arrow) and a clearer left nostril (green arrow). (b) The interaction between airflow rate and odorant sorption, which brings about a response in the olfactory nerve. (c) On each of ten trials, subjects were asked to smell an identical mixture of 50% octane and 50% L-carvone using either the left or right nostril. They were then given each individual odorant component to smell separately and judged the composition of the mixture by marking the line. Using the HF rate nostril (green), the average judgment was that the mixture consisted of 55% L-carvone and 45% octane. Using the LF rate nostril (red), the judgment was that it consisted of 61% octane and 39% L-carvone ($t(19) = 3.74$, $P = 0.001$).

Although some advantages have been suggested for right versus left nostril (Toulouse, E. and Vaschide, N., 1899; Koelega, H. S., 1979; Youngentob, S. L. *et al.*, 1982; Zatorre, R. J. and Jones-Gotman, M. 1990; Broman, D. A. *et al.*, 2001), and left versus right nostril (Homewood, J. and Stevens, R. J., 2001), no differences were found for HF versus LF nostrils (Eccles, R. *et al.*, 1989; Frye, R. E., 1995). This was paradoxical in view of the previously noted link between nasal airflow velocity and olfactory performance. Because increased velocity improves detection (Le Magnen, J., 1945; Laing, D. G. and Wilcox, M. E., 1983), and olfactory intensity estimates (Rehn, T., 1978; Teghtsoonian, R. and Teghtsoonian, M., 1984; Youngentob, S. L. *et al.*, 1986; Hornung, D. E. *et al.*, 1997), one would expect better olfactory performance in the HF nostril versus the LF nostril. Yet, no such differences were observed (Eccles, R. *et al.*, 1989; Frye, R. E., 1995). This paradox was resolved by Sobel N. *et al.* (2000a) who found that when humans are restricted to sniffing through one nostril only, if it is the LF nostril, they spontaneously increase sniff duration in that nostril so as to equate volume with the HF nostril. In other words, the olfactomotor system generates a compensatory sniff that accounts for the lower airflow in that nostril. Critically, Sobel N. *et al.*, found that once activation of this compensatory sniffing was prevented, olfactory performance was poorer in the LF nostril compared to the HF nostril (Sobel, N. *et al.*, 2000). Thus, the valid method for comparison of olfactory performance in the HF nostril versus the LF nostril is to assure that both sniff for the same duration (as they would have had one of them not been occluded for testing). This can be achieved by training subjects to match their sniff to either an auditory tone, or on-monitor measurement of nasal airflow (Mainland, J. D. *et al.*, 2005). With this in mind, Sobel N. *et al.* (1999) set out to test the hypothesis that the HF nostril and LF nostril would each be better tuned to a different aspect of an odor mixture. The framework for this hypothesis was set by the pioneering work of Mozell and colleagues, who demonstrated that odorants absorb in, and cross, the olfactory mucosa at different rates (Mozell, M. M. and Jagodowicz, M., 1973; Mozell, M. *et al.*, 1991). They established this phenomenon by measuring the relative sorption rates of 15 odorants across the mucosa of the bullfrog. Mozell and colleagues later found that the effect of an odorant on the magnitude of response in the olfactory nerve of the frog results from an interaction between the

particular sorption rate of that odorant and the flow rate at which it flows across the olfactory mucosa: a high-sorption rate odorant will induce a large response when delivered at a high airflow and a smaller response when delivered at a lower airflow. In contrast, a low-sorption rate odorant will induce a small response when delivered at a high airflow and a larger response when delivered at a lower airflow. A theoretical explanation to this is as follows: when a bolus of low-sorption odorant enters the nostril at a slow flow rate, there is a weak vector along the epithelium (slow flow) and a weak vector across the mucus (low sorption). This results in an even distribution of odorant molecules along the epithelium whereby a large epithelial surface area is affected, and the resulting response is large. In turn, when the same bolus of low-sorption odorant is flown rapidly across the mucosa, there is a strong vector along the epithelium (fast flow) and a weak vector across the mucus (low sorption). This results in a proportion of the molecules never sorbing before they are cleared into the respiratory system, an uneven distribution of odorant molecules along the epithelium whereby only the posterior end of the epithelial surface area is affected, and the resulting response is small. In contrast, when a bolus of high-sorption odorant enters the nostril at a slow flow rate, there is a weak vector along the epithelium (slow flow) and a strong vector across the mucus (high sorption). This results in an uneven distribution of odorant molecules along the epithelium whereby the full bolus saturates the anterior portion of the epithelium, a small epithelial surface area is affected, and the resulting response is small. In turn, when the same bolus of high-sorption odorant is flown rapidly across the mucosa, there is a strong vector along the epithelium (fast flow) and a strong vector across the mucus (high sorption) (Figure 11(b)). This results in an even distribution of odorant molecules along the epithelium whereby a large epithelial surface area is affected, and the resulting response is large.

The foregoing findings suggest that particular airflows will optimize perception for particular odorants. High airflows will optimize perception of higher-sorption rate odorants and low airflows will optimize perception of lower-sorption rate odorants. Considering these findings in the frog, one may predict that the difference in airflow rate between the nostrils in the human will result in a different olfactory percept in each nostril as a function of the interaction between airflow and odorant sorption rates. Accordingly, we hypothesized that the high-airflow nostril is better tuned to high-sorption rate odorants and the low-airflow nostril is better tuned to low-sorption rate odorants.

To test this, 20 subjects performed a task in which on each trial an olfactometer produced an equally proportioned mixture of the low-sorption rate odorant octane and the high-sorption rate odorant L-carvone (Figure 11(c)). Although subjects were deceived and told that the mixtures would be slightly different on every trial, they were actually identical mixtures. The subject then (1) took a monorhinal fixed-duration sniff of the mixture with either the HF rate nostril or LF rate nostril, (2) smelled each component odorant individually, and (3) judged the composition of the mixture on a proportion scale (ranging from 100% octane, to 50/50 octane/L-carvone to 100% L-carvone, as illustrated at bottom of Figure 11(c)). Each subject performed 20 trials with each nostril. All experimental components were counter-balanced to prevent confounds of cross-adaptation and learning.

Although the mixture was always the same, we predicted that when smelling the mixture with the high-airflow nostril, the high-sorption rate odorant would seem more prominent in the mixture, and when smelling the same mixture with the low-airflow nostril, the low-sorption rate odorant would seem more prominent. As predicted, 17 of the 20 subjects judged the same mixture to have a higher L-carvone content (high-sorption-rate odorant) when using the high-airflow nostril and a higher octane content (low-sorption-rate odorant) when using the low-airflow nostril (binomial, $P < .002$) (Figure 11(c)). This finding demonstrated that the olfactory content obtained from each nostril in a given sniff was different and related to sniff airflow. Each nostril was slightly better tuned to odorants that optimally sorb to the mucosa at the current flow rate in that nostril. This finding points to a fundamental commonality across distal sensory systems. In both vision and audition, the two sense organs simultaneously provide a slightly disparate image to the brain. In vision, this disparity is computationally manipulated to provide an additional dimension – depth. In audition, this disparity is computationally manipulated to provide an additional dimension – spatial location of sounds. We expect that the disparity of input across nostrils is similarly computationally manipulated to provide an additional dimension in olfaction. The nature of this olfactory dimension awaits characterization.

4.45.4.4 Identifying Odor Characteristics

Whereas odor identification can prove difficult, identifying particular odor characteristics or attributes is readily achieved. Even when they cannot identify an odor by name, subjects can generate descriptors for an odorant. Wise P. *et al.* (2000) have pointed to some limitations in assessing such behavior, such as (1) such judgments are difficult to verify, (2) different people may use widely different words to describe the same odors. This difference in language use across subjects can make it difficult to assess both interrater and intrarater agreement. Notwithstanding these issues, the analysis of subjective characteristics of odors provides a number of insights into how olfaction may be organized.

The most consistently agreed upon and meaningful characteristic of odors is their pleasantness, or valence as it is sometimes described. Whereas explicit identification, particularly of unfamiliar odors, can be relatively difficult, people can quite readily make judgments of odor pleasantness. Indeed, the primary perceptual aspect subjects use in odorant discrimination studies is odorant pleasantness (Schiffman, S. S. 1974; Godinot, N. and Sicard, G., 1995), and odor-grouping experiments show that pleasantness is the most salient dimension of olfaction (Berglund, B. *et al.*, 1973; Schiffman, S. *et al.*, 1977). Pleasant and unpleasant odors are evaluated at different speeds (Bensafi, M. *et al.*, 2002a) and act differentially on peripheral nervous responses (Jäncke, L. and Kaufmann, N., 1994; Brauchli, P. *et al.*, 1995; AlaouiIsmaili, O. *et al.*, 1997; AlaouiIsmaili, O. *et al.*, 1997; Bensafi, M., 2002b; 2002c; 2002d). Studies of startle reflexes suggest that unpleasant and pleasant smells might be mediated by at least two distinct fundamental emotional systems: an aversive system (associated with negative affects) and an appetitive one (associated with positive affects). According to Lang P. J. *et al.* (1990), activation of the aversive system might increase the magnitude of the startle reflex, while activation of the appetitive system might decrease the magnitude of the startle reflex. Odors have been used to produce positive and negative affective states during which unpleasant odors activate the aversive system and enhance startle reflexes (Miltner, W. *et al.*, 1994; Ehrlichman, H. *et al.*, 1995; 1997), whilst pleasant odors activate the appetitive system and attenuate startle reflexes (Ehrlichman, H. *et al.*, 1997). Startle in the presence of unpleasant odors may be a defensive behavior present early in life: in newborns, differential facial reactions have been found for pleasant and unpleasant odors (Steiner, J. E., 1979; Soussignan, R. *et al.*, 1997). The primacy of pleasantness judgments is also supported by electrophysiological recordings (Kobal, G. *et al.*, 1992; Pause, B. M. and Krauel, K. 2000; Masago, R. *et al.*, 2001) and functional neuroimaging studies (Zald, D. H. and Pardo, J. V., 1997; Fulbright, R. K. *et al.*, 1998; Crespo-Facorro, B. *et al.*, 2001; Henkin, R. I. and Levy, L. M., 2001; Gottfried, J. A. *et al.*, 2002a; 2002b).

Perceptually, odor valence is tightly linked with odorant intensity. In fact, the inverse correlation between odor intensity and valance is so pronounced that Henion K. E. (1971) suggested odor pleasantness and intensity are a single dimension. Henion based this claim on a study of a single odorant (*n*-amyl acetate). More comprehensive studies on the relationship between odor intensity and pleasantness, however, revealed a complex interaction whereby some odorants display a positive correlation (increased intensity leads to increased pleasantness), some an inverse correlation (increased intensity leads to decreased pleasantness), and yet others a variable inverted U-shaped correlation between pleasantness and intensity (Henion, K. E., 1971; Doty, R. L., 1975; Moskowitz, H. R. *et al.*, 1976; Distel, H. *et al.*, 1999) (Figure 12). The psychophysical data suggesting

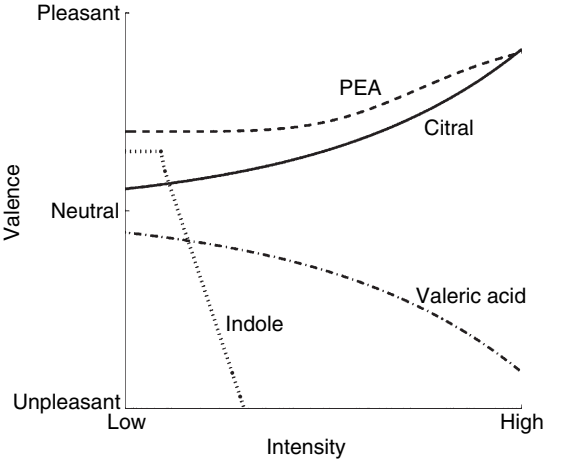

Figure 12 The relationship between intensity and valence. Different odors behave differently. Citral is pleasant, and as you increase its intensity, it becomes more pleasant. Valeric acid is unpleasant, and as you increase its intensity, it becomes more unpleasant. Phenyl ethyl alcohol (PEA) is pleasant, and this valence does not change much across a wide range of intensities, although it eventually does increase. Indole is pleasant at very low intensities, but even a relatively small increase in intensity shifts its percept to one that is extremely unpleasant.

intensity and valence are indeed dissociable constructs received support from neuroimaging studies that found olfactory intensity and valence are subserved by dissociable neural substrates (Gottfried, J. A. *et al.*, 2002b; Anderson, A. K. *et al.*, 2003; Anderson, A. K. and Sobel, N., 2003). Studies of olfactory psychophysics must consider this relationship in their design. For example, if one wants to probe intensity coding, one must keep valence constant, and vice versa.

4.45.4.5 Odor Space

In vision and audition, perceptual experience organizes itself, both through language and, directly, into an ordered space: perceptual events have a distinct relationship to one another that most people acknowledge. In vision, these organizational principles are so basic and ingrained, that they may scarcely need acknowledging: objects exist in a three-dimensional space with all the spatial relational operators, they have colors that can be ordered into a color wheel, so that colors themselves have a kind of spatial relationship. These basic facts arise from basic facts about the world: wavelengths of light, which map onto colors, themselves have an ordering, as does the nature of physical space. In audition, the sensory receptors are organized in the cochlea to map sound frequency onto a linear spatial gradient, and so within auditory perception, the experience of frequency has a linear ordering, namely pitch. That such a latent organization in the olfactory sensory apparatus may exist, and that it may map onto some intrinsic organizational principle within the set of olfactant molecules, has fueled numerous efforts to understand the olfactory odor space. These efforts are of two basic kinds: efforts to understand chemical features of molecules that may map onto perceptual differences and efforts to understand the structure of olfactory perceptual space itself, without reference to chemical properties. These different efforts are, of course, complementary, and the ultimate goal of each is to move from one to the other, so that specific changes in a perceptual space can be related to specific changes in molecular features. We will refer to these two kinds of efforts as stimulus-based maps and perception-based maps. We will first discuss the methods of acquiring feature information from these maps and subsequently discuss mathematical techniques usefully for reconstructing the maps from the information.

4.45.4.5.1 Perception-based maps

Attempts to assess the perceptual structure of olfaction have assumed there is an implicit set of features that are extracted by the nervous system from all odorants, and that these features can therefore be combined to form an olfactory space. The advantages of producing such maps is that from them unknown features of an odorant may be inferred from partial information, they can be used to investigate possible molecular features that correspond to underlying perceptual features, and they provide information about the possible organization of the olfactory nervous system.

All maps are connected to the idea of similarity: objects closer together in the perceptual space are more similar to each other than are objects further apart. Efforts to derive perceptual spaces can thus proceed in either of two ways: they can measure similarity between odorants directly and use this data to derive a map, or they can measure some other features of the objects and infer similarity from them indirectly and thus build a map. These two approaches can be thought of as explicit and implicit measures, depending on whether they measure or derive odorant similarity.

4.45.4.5.2 Explicit similarity methods

One approach to assessing similarity is having subjects group samples of odorants into categories. Odorants placed within the same category are judged to be more similar than odorants that span different categories. Subjects perform either a task where they place each odorant into one of the predefined categories to which it is most similar (Linneaus, C., 1756), or a task where they organize the odorants into any number of categories the subject deems appropriate (MacRae, A. W. *et al.*, 1990; 1992; Stevens, D. A. and O'Connell, R. J., 1996). The first method imposes a structure which may bias subjects and constrains the odor space (Lawless, H. T., 1989), but has the advantage of ensuring consistency of categories across subjects. Unrestricted sorting of odorants permits subjects greater freedom in expressing their perception, but there is greater intersubject variability, and the inconsistency of categories across subjects introduces further difficulties in combining subject data. However, this method appears reliable within subjects (MacRae, A. W. *et al.*, 1990; 1992), and certain differences in sorting might reflect true differences in perception by special subpopulations of subjects (Stevens, D. A. and O'Connell, R. J., 1996).

A second method is to present pairs of odorants and ask subjects to rate the similarity between them. The results from several such studies found considerable variability in judgments between subjects (Dimmick, F. L., 1927; Yoshida, M., 1964a; 1964b) but, as in the unrestricted sorting experiments, these differences may reflect true differences in perception (Dimmick, F. L., 1927; Gregson, R. M., 1972; Davis, R. G., 1979). Analysis of direct similarity scores suggest that in making judgments, subjects generally rely on a hedonic factor and several other factors which may vary across subjects (Yoshida, M., 1972a; 1972b; Moskowitz, H. R. and Gerbers, C. L., 1974; Schiffman, S. S. 1984). Part of this variability may result from a lack of specific instructions for similarity criteria (Wise, P. *et al.*, 2000). While useful for a relatively small set of odorants, the task becomes burdensome as the number of odorants increases, as the number of possible pairwise comparisons increases as the square of the number of odorants.

4.45.4.5.3 Implicit similarity methods

A second approach that is feasible for large sets of odorants is to instruct subjects to rate or rank odorants one at a time against a series of descriptors (e.g., verbal labels) (Dravnieks, A. *et al.*, 1978; Dravnieks, A., 1982; Laing, D. G. and Wilcox, M. E., 1983) and then inferring the similarity of pairs of odorants from their responses. This method assumes that similar odorants will have similar feature values, and thus will cluster together in the feature space. Dravnieks A. (1982) demonstrated that responses on a large set of semantic descriptors were stable across 150 subjects from 15 different locations across the United States. The use of a large set of descriptors reduces the concern that the choice of labels will limit the diversity of the method (Thiboud, M., 1991).

There are three large databases of odor category rankings available as commercial products – a strikingly small number considering the importance of such data and the uncertain reliability of these existing products. The largest and most comprehensive is the multivolume/compact-disc set by Steffen Actander. The Sigma-Aldrich Flavors & Fragrances Catalog contains a handful of odorant descriptors for each of 800 + chemicals. The most popular reference for obtaining odorant profiles is the Atlas of odor character profiles, which ranks 160 chemicals against each of the 146 descriptors (Dravnieks, A., 1985).

Once a full set of similarity data (either implicit or explicit) is available for a set of odorants, the organization of the result into a coherent odor space can be achieved through a variety of statistical methods. A common method for map reconstruction is with multidimensional scaling (MDS) (Kruskal, J. B. and Wish, M. 1978). We will only briefly introduce this method and leave the interested reader to seek out the provided references. The first step of MDS is to create an N by N distance matrix, where there are N odorants and the (i, j)th cell of the matrix contains the distance (the inverse of similarity) between the ith and jth odorants. The goal of MDS is to assign each odorant to a point in a metric space (typically Euclidean) so that the distance between odorants in this coordinate system preserves the distance structure in the original distance matrix (Figure 13). MDS is an iterative optimization algorithm that is often performed many times for high-dimensional spaces to reduce the chances of finding local minima. MDS is essential a data-compression technique, and there are many studies that set out to validate the technique for reducing olfactory perception data. The dimensionality of the constructed space must be specified as a prior constraint.

Using similarity ratings, several researchers found a primary pleasant–unpleasant dimension (Yoshida, M., 1972a; 1972b; Berglund, B. *et al.*, 1973;

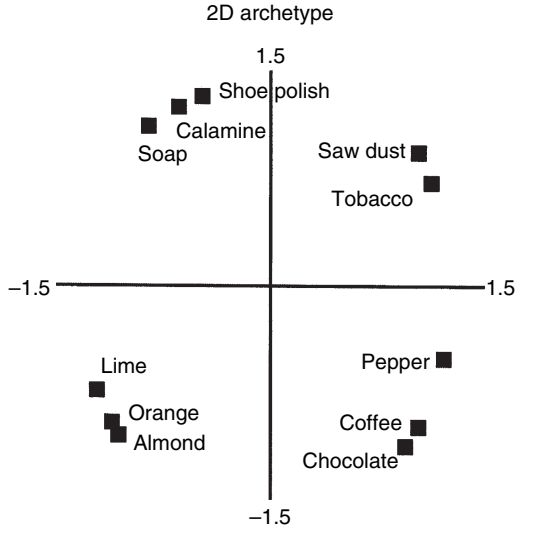

Figure 13 A two-dimensional multidimensional scaling (MDS) derived odor space for some common odors. The map is constructed from the similarity judgments of 110 subjects, so that the distances between odors in the MDS space is inversely proportional to perceived similarity. Although the axes are not meaningfully labeled, the odors cluster into sensible groups from Dawes, P. J. D., Dawes, M. T., *et al.* 2004. The smell map: commonality of odour perception confirmed. Clin. Otolaryngol. 29, 648–654.

Moskowitz, H. R. and Gerbers, C. L., 1974; Yoshida, M., 1975; Schiffman, S. *et al.*, 1977) and a secondary sweet-pungent dimension (Yoshida, M., 1964a; 1964b). The inability to associate more dimensions with perceptual qualities could be due to too few odorants or high subject variability that obscured everything except the most salient dimensions (e.g., hedonic value). Another weakness can be high between-subject variability for the underlying similarity ratings (Berglund, B. *et al.*, 1973). Cunningham M. and Crady C. A. (1971) used bipolar categories (e.g., pleasant or unpleasant or sour or sweet) instead of similarity ratings to probe the olfactory perceptual map and then used MDS to determine the most salient dimensions and found similar results in the salient dimensions.

Carrie S. *et al.* (1999) collected similarity reports for 20 normal and four hyposmic subjects on 11 common odors (i.e., coffee, chocolate, soap, and so on) and found very good agreement for the MDS maps of individual subjects. ALSCAL NMDS was used to compute a subject-weighted archetypal perception map. Individual subjects fit the archetypal map well, while the hyposmic did not. Dawes P. J. D. *et al.* (2004) repeated this experiment but used 110 new observers and found an almost identical MDS solution for the salient dimensions. However, the first three dimensions only accounted for 60% of response variance, suggesting either high variance between subjects, or that the odor space is in fact fairly high dimensional. Another source of this variance could be the known influence of olfactory sensitivity on perceptual quality (Stevens, D. A. and O'Connell, R. J., 1991).

Odor maps are also useful tools for understanding differences in perception across subjects. Stevens D. A. and O'Connell R. J. (1996) examined the perceptual map differences for three groups with differing sensitivity to the odorant pemenone. There are three typical perceptions of pemenone: putrid, nonputrid, and nondetection. Subjects responding in each of these ways were classified as osmic, allosmic, or anosmic, respectively. One hypothesis for these perceptual differences is differences in odorant receptor expression on the olfactory epithelium. Over 20 subjects from each group sorted 15 odorants (five putrid, five floral/fruity, and five wood/vegetable, note these are a priori groups created by the researchers and not based on the subjects) into any number of groups (e.g., free sorting). A similarity metric was created for each pair of odorants that was based on the percentage of subjects placing the pair in the same group. MDS was then used to project the distance matrix onto a three-dimensional space. The MDS created three clusters that reflected the three groups of odorants selected by the researchers (putrid, floral/fruity, and woody/vegetable). Additionally, the location of pemenone differed for each group of subjects. Pemenone was near the putrid cluster for osmics, near the vegetable/woody cluster for allosmics, and near the floral/fruity cluster for anosmics.

Perhaps the most extensive investigation of perceptual maps using MDS is by Chee-Ruiter and Madany-Mamlouk working in the laboratory of Jim Bower (Mamlouk, A. M., 2002; Mamlouk, A. M. *et al.*, 2003; Mamlouk, A. M. and Martinetz, T., 2004). Using the odor quality data in the Aldrich Flavor and Fragrances Catalog, Mamlouk computed the subdimensional distance (a weighted cross-entropy function) to estimate dissimilarity between the 851 odorants. The MDS solution suggested approximately 32 dimensions within the dissimilarity measurements, many more than typically presented in the MDS literature reviewed previously. When the solution was projected to a two-dimensional Euclidean space for visualization, distortions became apparent. Odorants that were not similar in the 32-dimensional solution became similar when collapsed, and some similarities were lost in the projection. In an interesting addition to the analysis, the number of nitrogen and sulfur atoms for each odorant emerged as the third dimension after the two-dimensional projection. The map shows that odorants containing nitrogen or sulfur were grouped together – supporting an eco-olfaction hypothesis in which metabolically relevant odorants are perceived similarly.

Altogether, efforts to understand the structure of the perceptual space reveal that a low dimensional description may be inadequate to capture the complexity of olfactory perception. Ultimately, the state of models of olfactory space is a half-finished project: the completion consists of connecting a space that represents meaningful features of perception with a physiological receptor space that represents the response of olfactory receptor cells to a given odor. This, of course, is no small task but is in fact tantamount to understanding a large part of all processing in the olfactory system. A fuller appreciation of the meaning of olfactory space models will emerge as progress towards this linkage bears fruit in future work.

4.45.4.6 Final Word

In this chapter, we have seen two things: first, that the human olfactory sensory system is an incredibly subtle molecular detector and discriminator; and second, that humans are an animal model particularly well suited for the study of what remains the biggest mystery in olfaction, namely the link between odorant structure and odorant percept. Whereas many other mammals exhibit olfactory detection and discrimination equal or better to that of humans, no other animal can convey its perception through language. Thus, for example, if one wanted to ask what properties of an odorant make it smell more like almonds, one could study nonhuman animals and devise complex behavioral tasks where one could only hope that decisions the animal would make (e.g., error rate or reaction time) might imply to what extent a given stimulus smells like almonds. However, any interpretation of animal behavior in this context is prone to error, as one can never be sure what stimulus features an animal is using in its decision process. This concern is increased due to the correlation between various olfactory features. For example, when studying intensity perception, how can we be sure that an animal is not basing its decisions in a task as a function of odorant valence rather than intensity, because these two dimensions of olfaction are tightly correlated. In contrast, when studying humans, the solution to such constraints is relatively easy. One can simply ask subjects: "which odorant smells more like almonds?". The power afforded by such a simple approach enables probing the more complex and essential questions of the qualities and similarities of odors. For these questions, the human model truly shines. With humans, not only can we learn much more about the percept because of language, but the datum of language use in connection with odors itself can be used to construct odor spaces that correlate with behavior. From the one side, the rules of biochemistry and physics govern how odorants react with olfactory receptors; from the other, there are rules of mind or perception. How they meet is the substance of psychophysics, and although the first bricks have been laid, the house remains to be built.

Glossary

accessory nerve The 11th cranial nerve (CN XI). This nerve controls specific muscles of the neck, namely the sternocleidomastoid muscle and the upper part of the trapezius muscle.

Addison's disease A rare endocrine disorder, also termed chronic adrenal insufficiency or hypocorticism, in which the body produces insufficient amounts of adrenal steroid hormones (glucocorticoids and often mineralocorticoids).

adrencorticotropic hormone A hormone, also termed ACTH or corticotrophin, produced and secreted by the pituitary gland. This hormone stimulates the cortex of the cortex of the adrenal gland and boosts the synthesis of corticosteroids, mainly glucocorticoids, but also adrenal sex steroids (androgens).

adrenocortical insufficiency The inability of the adrenal gland to produce adequate amounts of cortisol in response to stress. Also termed hypocortisolism.

agenesis The failure of an organ to develop during embryonic growth and development. Agenesis of key organs such as the heart and brain is usually fatal. However, for those organs which occur in pairs, the loss of one member (i.e., unilateral agenesis) is not.

ageusia The loss of taste functions of the tongue, particularly the inability to detect sweetness, sourness, bitterness, saltiness, and umami (the taste of monosodium glutamate).

albright hereditary osteodystrophy A disorder, also known as Martin–Albright syndrome, characterized by a lack of renal responsiveness to parathyroid hormone, resulting in low serum calcium, high serum phosphate, and high serum parathyroid hormone. Patients with this disorder have short stature, characteristically shortened fourth and fifth metacarpals, and rounded facies.

Alzheimer's disease The most common cause of dementia. Characterized by progressive cognitive deterioration, mainly loss of memory, together with declining activities of daily living and neuropsychiatric symptoms or behavioral changes. Neuronal loss or atrophy occurs largely in the temporoparietal cortex but also in the frontal cortex. Pathologically defined by abnormal deposition of amyloid plaques and neurofibrillary tangles.

amyotrophic lateral sclerosis (ALS; also known as Lou Gehrig's Disease) A progressive and ultimately fatal neurodegenerative disease caused by the gradual degeneration of CNS nerve cells that control voluntary muscle movement. Both the upper motor neurons and the lower motor neurons degenerate or die, ceasing to send messages to muscles. The muscles gradually weaken, waste away (atrophy), and have fasciculations (twitches) because of denervation. Eventually, the brain completely loses its ability to initiate and control voluntary movement.

aneurysm A localized, blood-filled dilation (bulge) of a blood vessel caused by disease or weakening of the vessel wall. Cerebral aneurysms most commonly occur in arteries at the base of the brain (the circle of Willis).

angiotensin-converting enzyme An enzyme that catalyzes the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor, and participates in the inactivation of bradykinin, a potent vasodilator. These two actions make it an ideal target in the treatment of conditions such as high blood pressure, heart failure, diabetic nephropathy, and type 2 diabetes mellitus.

anorexia nervosa An eating disorder characterized by low body weight and body image distortion with an obsessive fear of gaining weight. Individuals with anorexia often control body weight by voluntary starvation, purging, vomiting, excessive exercise, or other weight control measures, such as diet pills or diuretic drugs.

anosmia The lack of the ability to smell. It can be either temporary or permanent.

anterior olfactory nucleus A nucleus located in the posterior part of the olfactory bulb which serves as a relay between some projection neurons of the bulb and other brain regions, including the contralateral olfactory bulb and cortex.

antihyperlipidemic drugs A diverse group of lipid-lowering drugs used in the treatment of hyperlipidemias. There are several classes of antihypolipidemic drugs which differ in their impact on the cholesterol profile and in adverse side effects. Examples include statins, fibrates, niacin, bile acid sequestrants (resins), and drugs that inhibit cholesterol absorption.

antihypertensive drugs A class of drugs used in medicine and pharmacology to treat hypertension (high blood pressure). There are many classes of antihypertensives which act by varying means to lower blood pressure.

ataxia A neurological sign and symptom consisting of unsteady and clumsy motion of the limbs and torso, due to a failure of the gross coordination of muscle movements, most evident on standing and walking.

auriculotemporal nerve A branch of the mandibular nerve that runs with the superficial temporal artery and vein, and provides sensory innervation to various regions on the side of the head.

autonomic nervous system That part of the peripheral nervous system that controls homeostatic maintenance of the body's internal state. Also termed the visceral nervous system.

Bardet–Biedl syndrome A genetic multi-system disorder that can cause chronic and end-stage renal failure in children. It is characterized by obesity, limb deformities, cognitive impairment, and genitourinary tract malformations. Despite its rarity, this syndrome has come to recent prominence because of the primary cilia dysfunction underlying its pathogenesis.

basal ganglia A group of brain nuclei, sometimes termed the basal nuclei, which are interconnected with the cerebral cortex, thalamus, and brainstem. Mammalian basal ganglia are associated with a variety of functions, including motor control, cognition, emotions, and learning, and are known to be compromised in Parkinson's disease.

bulemia nervosa A psychological eating disorder in which recurrent binge eating is followed by intentional purging. This purging is done to compensate for the excessive intake of food, usually to prevent weight gain. Purging can take the form of vomiting; inappropriate use of laxatives, enemas, diuretics, or other medication; or excessive physical exercise.

burning mouth syndrome A condition, also termed glossodynia, characterized by a burning or tingling sensation on the lips, tongue, or entire mouth. Typically, there are no visual signs like discoloration to aid in the diagnosis.

chorda tympani nerve A branch of the facial nerve (cranial nerve VII) that carries sensory fibers providing taste sensation from the anterior two-thirds of the tongue, as well as presynaptic parasympathetic fibers to the submandibular ganglion that provide secretomotor innervation to the submandibular and sublingual salivary glands.

cribriform plate A portion of the ethmoid bone separating the brain cavity from the nasal cavity and through which the olfactory nerves project.

cryptorchidism The absence from the scrotum of one or both testes.

Cushing's syndrome A rare endocrine disorder caused by high blood levels of cortisol, a hormone relesed from the adrenal gland in response to ACTH from the pituitary gland. Also termed hypercortisolsim or hyperadrenocorticism.

Down syndrome A genetic disorder, previously termed mongolism, caused by the presence of all or part of an extra 21st chromosome (trisomy 21). Mental retardation and physical growth changes are typical characteristics.

dysgenesis Abnormal development of a tissue or other body part.

dysosmia A disordered smell quality, such as the odor of roses smelling like feces.

dysgeusia A disordered taste quality, such as salt tasting bitter.

ethmoidal Nerve A branch of the trigeminal nerve. The anterior ethmoidal nerve provides somatosensation to the nasal cavity.

facial nerve The 7th cranial nerve (CN VII). It emerges from the brainstem between the pons and the medulla. This nerve controls the muscles of facial expression and innervates the taste buds on the anterior two-thirds of the tongue via the chorda tympani nerve branch. It also supplies preganglionic parasympathetic fibers to several head and neck ganglia.

frontal lobe An area in the brain of vertebrates located at the front of each cerebral hemisphere. The frontal lobes play a part in impulse control, judgment, language production, working memory, motor function, problem solving, sexual behavior, socialization, and spontaneity, and are critical for normal planning, coordinating, controlling, and executing of a range of behaviors.

frontal operculum The most posterior portion of the inferior frontal gyrus of the frontal lobe. One famous part of the operculum is Broca's area which plays an important role in conversation or speech production, reading, and writing.

glossalgia Same as glossadynia; see burning mouth syndrome.

glossopharyngeal nerve The 9th cranial nerve. This nerve exits the brainstem from the sides of the upper medulla, just rostral (closer to the nose) to the vagus nerve. This nerve supplies the taste buds on the posterior third of the tongue.

Huntington's disease A rare inherited neurological disorder caused by a trinucleotide repeat expansion in the Huntingtin (Htt) gene. This expansion produces an altered form of the Htt protein, mutant Huntingtin (mHtt), which results in neuronal cell death in select areas of the brain. Its most obvious symptoms are abnormal body movements called chorea and a lack of coordination, but mentation and some aspects of personality also can be affected.

hypogeusia Diminished taste sensitivity.

hypoglossal nerve The 12th cranial nerve (XII). This nerve supplies motor fibres to all of the muscles of the tongue, except the palatoglossus muscle which is innervated by the vagus nerve (X) and the accessory nerve (XI).

hypogonadotropic hypogonadism A disorder characterized by a failure of the function of the gonads (ovaries or testes), resulting in hormonal deficiency and infertility. Deficiency of the sex hormones can result in defective primary or secondary sexual development, or withdrawal effects (e.g., premature menopause) in adults.

hypoparathyroidism Decreased function of the parathyroid glands, leading to decreased levels of parathyroid hormone (PTH). The consequence, hypocalcemia, is a serious medical condition.

hyposmia Diminished smell function.

hypothyroidism A disease state caused by insufficient production of thyroid hormone by the thyroid gland.

iatrogenesis Literally means ''brought forth by a healer'' (*iatros* means healer in Greek). As such, it can refer to good or bad effects, but it is almost exclusively used to refer to a state of ill health or adverse effect or complication caused by or resulting from medical treatment.

insular cortex A brain structure that lies deep to the brain's lateral surface within the lateral sulcus, a groove which separates the temporal lobe and inferior parietal cortex. The latter overlying cortical areas are known as opercula (meaning ''lids''), and parts of the frontal, temporal, and parietal lobes form opercula over the insular cortex (also termed insula).

internal capsule An area of brain white matter that separates the caudate nucleus and the thalamus from the lenticular nucleus. It consists of axonal fibers that run between the cerebral cortex and the pyramids of the medulla.

Kallmann syndrome A syndrome characterized by anosmia and hypogonadism (decreased functioning of the sex hormone-producing glands) caused by a deficiency of gonadotropin-releasing hormone (GnRH) in the hypothalamus. Also known as hypothalmic hypogonadism with anosmia, familial hypogonadism with anosmia, or hypogonadotropic hypogonadism with anosmia.

lingual nerve A branch of the mandibular nerve (CN V3), itself a branch of the trigeminal nerve. This nerve supplies sensory innervation to the mucous membrane of the anterior two-thirds of the tongue. It also carries non-trigeminal nerve fibers, including those responsible for taste sensation on the anterior tongue and both parasympathetic and sympathetic fibers to the submandibular ganglion, a structure suspended by two nerve filaments from the lingual nerve.

lymphedema A condition of localized fluid retention caused by a compromised lymphatic system. The lymphatic system (often referred to as the body's ''second'' circulatory system) collects and filters the interstitial fluid of the body.

magnetoencephalography An imaging technique used to measure the magnetic fields produced by electrical activity in the brain via extremely sensitive devices such as superconducting quantum Interference devices (SQUIDs). There are many uses for the MEG, including assisting surgeons in localizing a pathology, assisting researchers in determining the function of various parts of the brain, neurofeedback, and others.

meningioma Common benign tumors of the brain (95% of benign tumors) that can occasionally be malignant. They arise from the arachnoidal cap cells of the meninges and represent about 15% of all primary brain tumors.

midbrain The mesencephalon (or midbrain) is the middle of three vesicles that arise from the neural tube that forms the brain of developing animals.

Caudally the mesencephalon adjoins the pons (metencephalon) and rostrally it adjoins the diencephalons, a brain region containing the thalamus, hypothalamus, and other structures.

migraine A neurological disorder associated with an electrochemical change in the trigeminovascular regions of the brain. The most common symptom is an intense and disabling episodic headache. Migraine headaches are usually characterized by severe pain on one or both sides of the head as well as a multitude of potential neurological symptoms.

multiple sclerosis A chronic, inflammatory, demyelinating disease that affects the central nervous system (CNS). Symptoms can include sensory problems (most notably visual and balance problems), muscle weakness, depression, difficulties with coordination and speech, severe fatigue, cognitive impairment, overheating, and pain. MS causes impaired mobility and disability in more severe cases.

nucleus tractus solitarius The solitary nucleus and tract are structures in the brainstem that carry and receive visceral sensation and taste from the facial (VII), glossopharyngeal (IX), vagus (X) cranial nerves, as well as the cranial part of the accessory nerve (XI).

olfactory reference syndrome A psychiatric condition of excessive concern with odors, usually imagined. The disorder can be accompanied by shame, embarrassment, significant distress, avoidance behavior, and social isolation.

Parkinson's disease A degenerative disorder that often impairs motor skills and speech. It is classically characterized by muscle rigidity, tremor, a slowing of physical movement (bradykinesia) and, in extreme cases, a loss of physical movement (akinesia). The motor symptoms result from decreased dopamine within the basal ganglia, thereby reducting stimulation of the motor cortex. Secondary symptoms can include high level cognitive dysfunction and subtle language problems.

pons A central nervous system structure located on the brainstem above the medulla oblongata, below the midbrain, and anterior to the cerebellum. This structure relays sensory information between the cerebellum and cerebrum, and contains the pneumotaxic centers that regulate respiration. some theories pose that it has a role in dreaming.

postcentral gyrus The lateral postcentral gyrus is a prominent structure in the parietal lobe of the human brain and an important landmark. Often referred to as primary somatosensory cortex, as it received the bulk of the thalamocortical projection from the sensory input fields.

precentral gyrus The primary motor cortex (or M1) works in association with pre-motor areas to plan and execute movements. M1 contains large neurons known as Betz cells which send long axons down the spinal cord to synapse onto alpha motor neurons which connect to the muscles. Pre-motor areas are involved in planning actions (in concert with the basal ganglia) and refining movements based upon sensory input (this requires the cerebellum).

Primary olfactory cortex Cortical regions (e.g., entorhinocortex and pyriform cortex) that receive the initial projections from the olfactory bulb.

progressive supranuclear palsy A rare degenerative disorder involving the gradual deterioration and death of selected areas of the brain. The initial symptom in most cases is loss of balance and falls. Other common early symptoms are changes in personality or general slowing of movement. Later symptoms and signs are dementia (typically including loss of inhibition and ability to organize information), slurring of speech, difficulty swallowing, and difficulty moving the eyes, most specifically in the downward direction.

pseudohypoparathyroidism A condition caused by resistance to the parathyroid hormone. Patients have a low serum calcium and high phosphate, but the parathyroid hormone level is appropriately high.

schizophrenia A mental illness characterized by impairments in the perception or expression of reality, most commonly manifesting as auditory hallucinations, paranoid or bizarre delusions, or disorganized speech and thinking in the context of significant social or occupational dysfunction.

seasonal affective disorder An affective, or mood, disorder. Most sufferers experience normal mental health throughout most of the year, but experience depressive symptoms in the winter or summer.

sella turcica A saddle-shaped depression in the sphenoid bone at the base of the human skull. The seat of the saddle is known as the hypophyseal fossa which holds the pituitary gland.

striatum A subcortical part of the telencephalon. It is the major input station of the basal ganglia system. Anatomically, the striatum is comprised of the caudate and the putamen.

sulfhydryl group A functional group on a molecule composed of a sulfur and a hydrogen atom (–SH).
superior temporal gyrus The superior temporal gyrus is one of three (sometimes two) gyri in the temporal lobe of the human brain. A gyrus (plural gyri) is a bump or ridge on the surface of the brain.
temporal lobe These elements of the cerebrum lie at the sides of the brain, beneath the lateral or Sylvian fissure. Seen in profile, the human brain looks something like a boxing glove. The temporal lobes are where the thumbs would be. The temporal lobe is involved in sensory processing, as well as in semantics both in speech and vision. The temporal lobe contains the hippocampus and is therefore involved in memory formation as well.
thalamus A paired and symmetric deep portion of the brain which relays sensory information from sensory systems to various areas of the cortex. It constitutes the main part of the diencephalon.
trigeminal nerve The fifth cranial nerve (CN V). This nerve is responsible for sensation in the face, eyes, and oral cavity, and can respond to some chemicals, producing such sensations as cooling, sharpness, and warmth.
Turner syndrome This disorder occurs in 1 in 2500 female births. Instead of the normal XX sex chromosomes for a female, only one X chromosome is present and fully functional. A normal female karyotype is labeled 46, XX; individuals with Turner syndrome are 45, X (also labeled 45, X0 or less commonly X(,)) though other genetic variants occur. In Turner syndrome, female sexual characteristics are present but generally underdeveloped.
uremia A toxic condition resulting from renal failure, when kidney function is compromised and urea (a waste product normally excreted in the urine) is retained in the blood. Uremia can lead to disturbances in the platelets and hypersomnia, among other problems.
vagus nerve The 10th cranial nerve (CN X). This nerve starts in the brainstem (within the medulla oblongata) and extends, through the jugular foramen, down below the head, to the abdomen. The vagus nerve is responsible for such varied tasks as heart rate, gastrointestinal peristalsis, sweating, and quite a few muscle movements in the mouth, including speech (via the recurrent laryngeal nerve) and keeping the larynx open for breathing. It also receives some sensation from the outer ear, via the auricular branch (also known as Alderman's nerve) and part of the meninges. Taste buds at the back of the throat are innervated by this nerve.
vestibular nuclei The cranial nuclei for the vestibular nerve.

> ". . .smell and taste are in fact but a single composite sense, whose laboratory is the mouth and its chimney the nose. . .." Jean Anthelme Brillat-Savarin, 1826

4.46.1 Introduction

The senses of taste and smell warn us of toxins, such as spoiled food, leaking natural gas, polluted air, and smoke. Moreover, as noted above by Brillat-Savarin, author of *Physiologie du Gout*, these senses work together in their production of flavor sensations. This is why many people mistake the olfaction-related experiences derived from eating (e.g., the sensations of chocolate, strawberry, lemon, etc.), which depend upon stimulation of the olfactory receptors via the retronasal route, as emanating from the taste buds. In fact, taste buds only mediate the sensations of sweet, sour, salty, bitter, and possibly metallic (iron salts), umami (sodium salts), and chalky (calcium salts). Like primary colors, smell and taste sensations blend to create variable hues of chemosensory experience, and when combined with the sensory input from the trigeminal system, ingested substances acquire an aroma, texture, temperature, and spiciness, allowing for the overall perception of flavor.

Damage to the olfactory and gustatory systems can profoundly influence a patient's quality of life. Persons without a sense of smell can no longer enjoy the nuances of perfume, wine, and fine food, in some cases leading to depression and, depending upon the individual, weight loss or weight gain. Taste dysfunction, commonly presenting as an abnormal taste, may significantly affect food choices and adversely alter nutrient intake. Chemosensory dysfunction is particularly disabling for those who depend upon these

senses for their livelihood or safety, including plumbers, fire fighters, policemen, perfumers, and workers within the food and beverage industries. Surprisingly, disorders of taste and smell are common, being present in at least 1% of the population under the age of 65 years, and well over 50% of the population over the age of 65 years (Doty, R. L. *et al.*, 1984a; 1984b; Hoffman, H. J. *et al.*, 1998).

In this chapter, we review a number of human chemosensory disorders, present up-to-date practical techniques for their management and quantitative evaluation, and describe how they are classified, evaluated, and treated. This survey is not inclusive, and examples are presented only to show the relationship between specific disease states and chemosensory disturbances.

4.46.2 Anatomy of Human Taste and Smell Systems

Chemosensory dysfunction can arise from disorders that block delivery of stimuli to receptors, as well as from ones that damage neural processes at various levels of the sensory system. In the vast majority of cases of olfactory dysfunction, damage occurs to the olfactory membrane. The most typical site of taste dysfunction is generally less clear, although taste buds can be directly altered via injury to the lingual surfaces. Since the neural circuitry involved in olfactory and gustatory perception is complex, a basic overview of the anatomy of these systems is presented in this section to place clinical issues into perspective; more detailed descriptions of the biochemistry and physiology of these systems are found elsewhere in this volume.

4.46.2.1 Olfactory Pathways

Six to ten million olfactory receptor cells, collectively termed cranial nerve I (CN I), are located within the approximately $2\,cm^2$ pseudostratified columnar epithelium lining the region of the cribriform plate and sectors of the superior turbinate, middle turbinate, and superior septum. In the human, about 350 receptors are distributed across these millions of cells, localized to cilia extending from dendritic knobs into the overlying mucus (Rouquier, S. *et al.*, 2000). The axons of the receptor cells unite to form bundles of 30 to 50 fila ensheathed by glial cells that traverse the cribriform plate and pia matter to form the outermost layer of the olfactory bulb. The axons of the olfactory receptors enter the glomeruli of the second layer of the olfactory bulb, where they form multiple synapses with the dendrites of the mitral and tufted cells, the bulb's primary projection neurons. The olfactory bulb is a layered structure that serves as the first relay system in the olfactory pathway. The bulb transforms the incoming signal, sharpening the information relative to the mix of chemicals involved and bodily state (e.g., hunger). In addition to sending afferents directly to the olfactory cortex via the lateral olfactory tract, the mitral and tufted cells send collaterals that synapse within the periglomerular and external plexiform layers of the bulb, where efferent influences from central structures can occur.

The primary olfactory cortex (POC), the direct recipient of the bulbar afferents, is comprised of the anterior olfactory nucleus (AON), the piriform cortex, the olfactory tubercle, the entorhinal area, the periamygdaloid cortex, and the corticomedial amygdala (Figure 1). While the majority of olfactory bulb neurons project to the piriform cortex, found within the medial portion of the temporal lobe, other fibers project directly to structures of the limbic system involved in memory and emotion (e.g., entorhinal cortex, periamygdaloid complex, and subsequently the hippocampus). Some projections occur, via the anterior commissure, from pyramidal cells of the AON to contralateral elements of the POC. Contralateral, as well as ipsilateral, activity is present, although generally the ipsilateral activity is more intense and rapid, as measured, for example, by magnetoencephalography (MEG) (Tonoike, M. *et al.*, 1998). Olfaction differs from the other senses in sending projections to the cortex that do not relay first within the thalamus. Thalamic connections do exist, however, between projections to and from the primary and secondary olfactory cortices.

4.46.2.2 Gustatory Pathways

Taste receptors are mostly found within taste buds located on lingual protuberances, termed papillae. Some taste buds are found on the epiglottis and soft palate. The receptor elements within the buds are innervated by branches of the facial (CN VII), glossopharyngeal (IX), and vagus (CN X) nerves, depending upon the bud's location within the oral cavity (Figure 2). Unlike CN I, these cranial nerves are mixed motor and sensory nerves. This becomes important when considering clinical syndromes that involve taste dysfunction, since variable degrees of

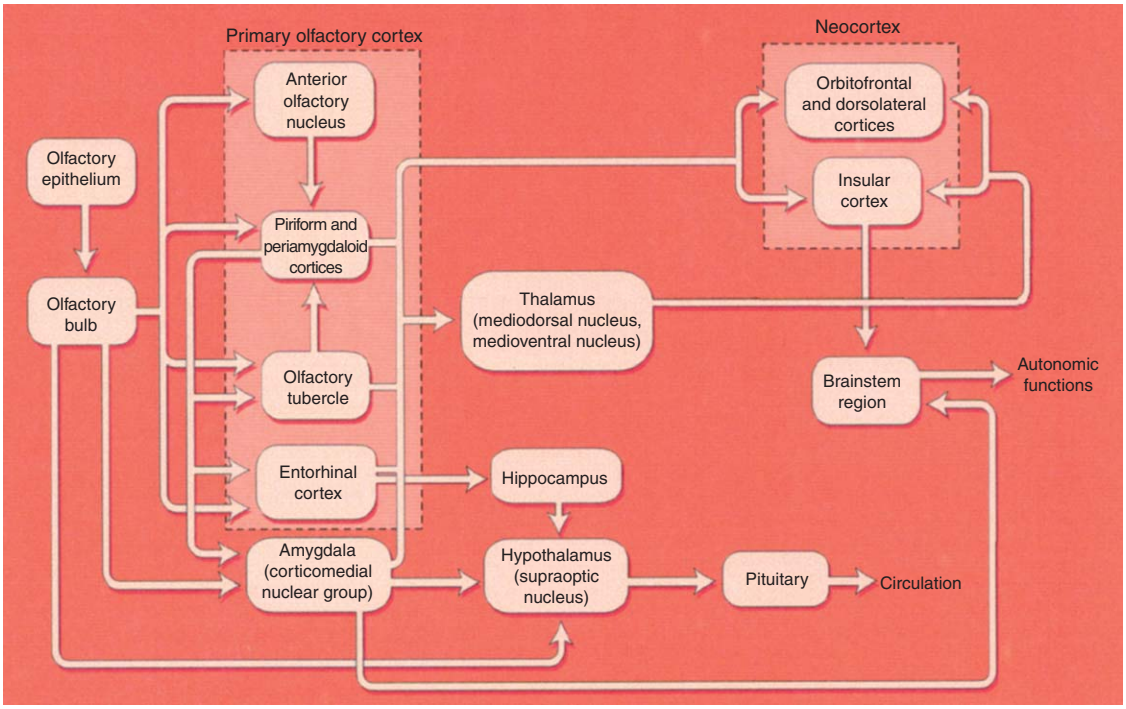

Figure 1 Primary afferent neural connections of the human olfactory system. Although olfactory fibers project from the amygdala to the feeding center of the hypothalamus, particularly the ventromedial and ventrolateral nuclei, it is unclear whether direct olfactohypothalamic routes are available in humans, as occurs in some other mammals. Copyright © 1996, Richard L. Doty.

either motor or sensory disturbance may be present depending upon where and to what extent the taste-mediating cranial nerve is injured.

All the peripheral gustatory fibers enter the brainstem and project to the nucleus of the tractus solitarius (NTS), which begins in the rosterolateral medulla and extends caudally along the ventral border of the vestibular nuclei. The major cortical projections from the NTS are to insular and perisylvian cortical regions, including the frontal operculum, superior temporal gyrus (opercular part), and inferior parts of the pre- and postcentral gyrus (Gloor, P., 1997; Faurion, A. *et al.*, 1998). A secondary cortical taste region is located in the caudomedial/caudolateral orbitofrontal cortex rostral to the primary taste cortex (Baylis, L. L. *et al.*, 1995). A number of such regions process touch and temperature, in addition to taste. The cells of the NTS also make viscerovisceral and viscerosomatic reflexive connections, via the interneurons of the reticular formation, with cranial nuclei that control (1) the muscles of facial expression; (2) taste-mediated behaviors, including chewing, licking, salivation, and swallowing; and (3) preabsorptive insulin release (Smith, D. V. and Shipley, M. T., 1992).

4.46.2.3 Trigeminal System

Free nerve endings from the trigeminal nerve (CN V) are found throughout the nasal and oral cavities. In the nose, they are responsible for somatosensory sensations induced by some odorants (e.g., stinging, sharpness, coolness, and warmth), whereas in the mouth, they contribute to the tactile, thermal, and spicy sensations essential for many flavor sensations. Anatomically, the anterior and lateral sectors of the nasal cavity are innervated by lateral and medial nasal branches of the ethmoidal nerve. The posterior region of the nasal cavity is innervated by the nasopalatine nerve. The gustatory fibers of the facial nerve (chorda tympani) travel in conjunction with the mandibular trigeminal fibers of the lingual nerve for a short distance near the tongue, making both of these nerves susceptible to orofacial causes of injury.

4.46.3 Symptoms of Chemosensory Dysfunction

The symptoms of chemosensory dysfunction can range from total loss of smell or taste perception

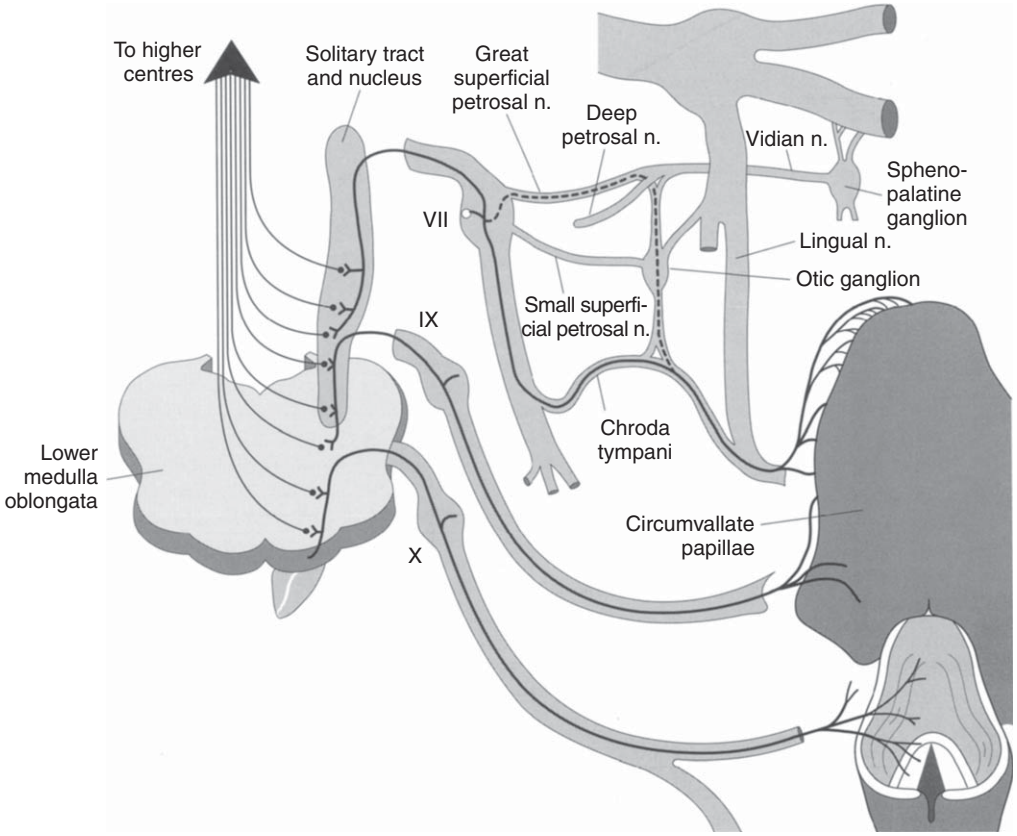

Figure 2 Distribution of cranial nerves to gustatory regions. CN VII fibers from the geniculate ganglion innervate taste buds on the anterior tongue and soft palate. CN IX fibers from cell bodies within the petrosal ganglion innervate taste bud on the lingual foliate and vallate papillae, as well as pharyngeal taste buds. CN X fibers from cell bodies in the nodose ganglion innervate taste buds on the epiglottis, larynx, and esophagus. Modified from Netter, F. H. 1964. The Ciba Collection of Medial Illustrations, Vol. 1, Nervous System. Ciba Pharmaceutical Corporation.

(termed anosmia and ageusia, respectively) to persistent and debilitating sensory disturbances, such as the presence of a strong and persistent salty taste (dysgeusia) or a bad smell (dysosmia). When such sensations appear without any apparent stimulus, they are termed phantogeusias or phantosmias, respectively. In most cases where a patient complains of chemosensory problems, some degree of smell or taste loss is apparent upon quantitative testing. In a few cases, however, disturbances in the perception of tastes or smells occur that cannot be objectively detected. A debilitating disorder, often associated with taste distortions that are not detectable by taste tests, is that of burning mouth syndrome (BMS; also known as glossodynia or glossalgia). In this syndrome, the patient experiences intense oral burning pain on the tongue or elsewhere within the oral cavity (Grushka, M. and Sessle, B. J., 1991).

4.46.4 Clinical Evaluation of Chemosensory Disorders

4.46.4.1 Medical History and Examination

The etiology of most cases of chemosensory dysfunction can be ascertained from carefully questioning the patient about the nature, timing, onset, duration, and pattern of symptoms, as well as a historical determination of antecedent events, such as head trauma, upper respiratory infections (URIs), toxic exposures, nasal or oral surgeries, and so on. A history of epistaxis, discharge (clear, purulent, or bloody), nasal obstruction, and somatic symptoms, including headache or irritation, may aid in establishing the probable etiology. Fluctuations in olfactory function usually reflect obstructive, rather than neural, factors. It is important to identify exacerbating or relieving foods or products, prior treatments and their efficacy

and comorbid medical conditions (e.g., liver disease, kidney disease, hypothyroidism, diabetes, and vitamin deficiencies). Delayed puberty in association with anosmia, with or without midline craniofacial abnormalities, deafness, and renal anomalies, suggests the possibility of Kallmann's syndrome or one of its variants. Patients who report never having had a sense of smell typically lack normal olfactory bulbs or tracts upon appropriate magnetic resonance imaging (MRI) studies (Li, C. *et al.*, 2003). Medications being used prior to or at the time of the symptom should be identified, particularly when taste, per se, appears to be altered. Such widely used drugs as statins, antifungal agents, and angiotensin-converting enzyme (ACE) inhibitors commonly cause chemosensory disturbances, most notably alterations in taste perception. Although dysosmias or phantosmias usually reflect alterations at the level of olfactory epithelium, in rare cases they signify central tumors or lesions that can be associated with tremor or seizure activity (e.g., automatisms, occurrence of black-outs, auras, and déjà vu).

Problems with speech articulation, salivation, chewing, swallowing, oral pain or burning, dryness of the mouth, periodontal disease, foul breath odor, recent dental procedures or surgeries, recent radiation exposure, medications, and bruxism can aid in establishing the basis of a taste problem. Inquiry into the patient's diet and oral habits may reveal exposure to oral irritants. Questions about hearing, tinnitus, and balance are important since the vestibulocochlear nerve (CN VIII) travels in close proximity to the facial nerve and can be susceptible to similar etiologies of disturbance (e.g., cerebellopontine angle tumors). Considering the occasional effect of gastroesophageal reflux on taste, asking about stomach problems may also be relevant. Constitutional symptoms – such as fever, malaise, headache and body pains, and rashes – may also be important since such symptoms often accompany cancers or systemic inflammatory conditions (e.g., lupus).

4.46.4.2 Quantitative Chemosensory Testing

A common error made on the part of clinicians is to accept a patient's report of olfactory dysfunction and to fail to objectively verify the presence or magnitude of the problem. Unfortunately, many persons are inaccurate in assessing the magnitude of their dysfunction, particularly the elderly or those with dementia. As noted in the introduction, a large number of patients confuse the loss of flavor sensations derived from the loss of olfactory function with taste, misleading themselves and their physicians as to the sensory system involved in their dysfunction (Figure 3). Some patients, particularly ones involved in litigation, attempt to malinger or overstate the nature of their dysfunction. Quantitative testing allows for a determination of the nature and degree of the chemosensory problem, the detection of malingering, and the tracking of changes in function over time and the efficacy of medical or surgical interventions.

Practical tests of smell function are now commercially available (for review, see Doty, R. L. 2001). The most widely used of such tests, the University of Pennsylvania smell identification test (UPSIT), has been administered to hundreds of thousands of patients and has been translated into a number of non-English languages. This test provides an indication of absolute smell loss, as well as the degree of smell loss relative to a patient's age and gender (i.e., percentile rank). The latter is critical, since smell ability decreases markedly in the later years (Figure 4). Electrophysiological tests, such as the odor event-related potential, can aid in the detection of malingering, although, unlike their auditory counterpart, they are presently unable to discern where in the olfactory pathway an anomaly exists. Although direct electrical recordings from the olfactory neuroepithelium can be made (termed the electro-olfactogram), such recordings can be misleading. Thus, anosmic patients lacking olfactory bulbs and tracts (e.g., those with Kallmann's syndrome), as well as patients with clearly determined psychophysical olfactory dysfunction (e.g., those with schizophrenia), commonly have clear electro-olfactograms.

Numerous taste tests are described in the literature that can be used to detect taste dysfunction, perhaps the most practical being that of electrogustometry. Testing of specific regions of the tongue is usually desired, since whole-mouth tests can be relatively insensitive to a number of gustatory alterations, given the redundancy of the innervation of the taste buds (for review, see Frank, M. E. *et al.*, 1995).

4.46.5 Causes of Chemosensory Dysfunction

Although there are reports of hundreds of disorders associated with chemosensory disturbance, a number of such reports are anecdotal and require empirical validation. Olfactory dysfunction can reflect, among other things, (1) altered airflow to the olfactory

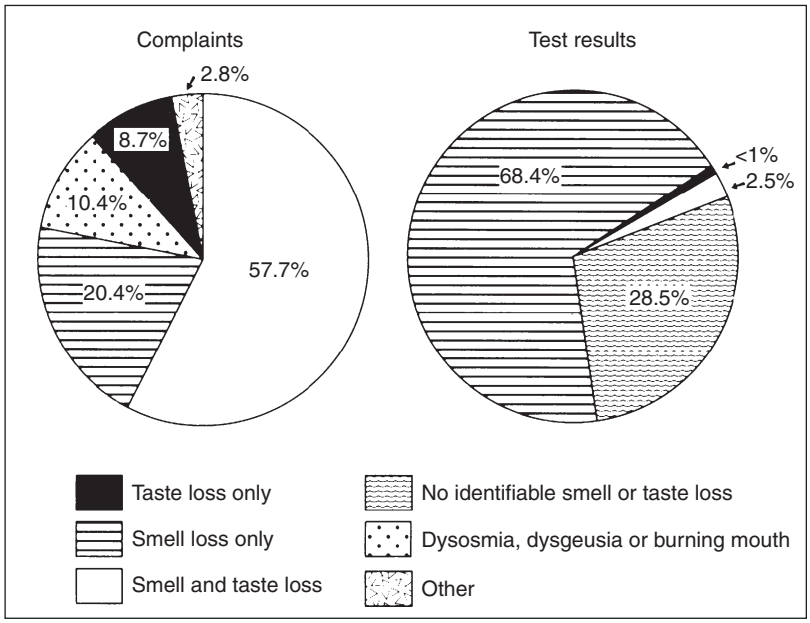

Figure 3 Distribution of primary chemosensory complaints (left diagram) and test results (right diagram) in 750 consecutive patients presenting to the University of Pennsylvania Smell and Taste Center for chemosensory evaluation. Note that the complaint categories of smell loss, taste loss, and smell and taste loss include some patients with secondary complaints of chemosensory distortion and burning mouth from Deems, D. A., Doty, R. L., Settle, R. G., Moore-Gillon, V., Shaman, P., Mester, A. F., *et al.*, 1991. Smell and taste disorders, a study of 750 patients from the University of Pennsylvania Smell and Taste Center. Arch. Otolaryngol. Head Neck Surg. 117, 519–528. Copyright © 1991, American Medical Association.

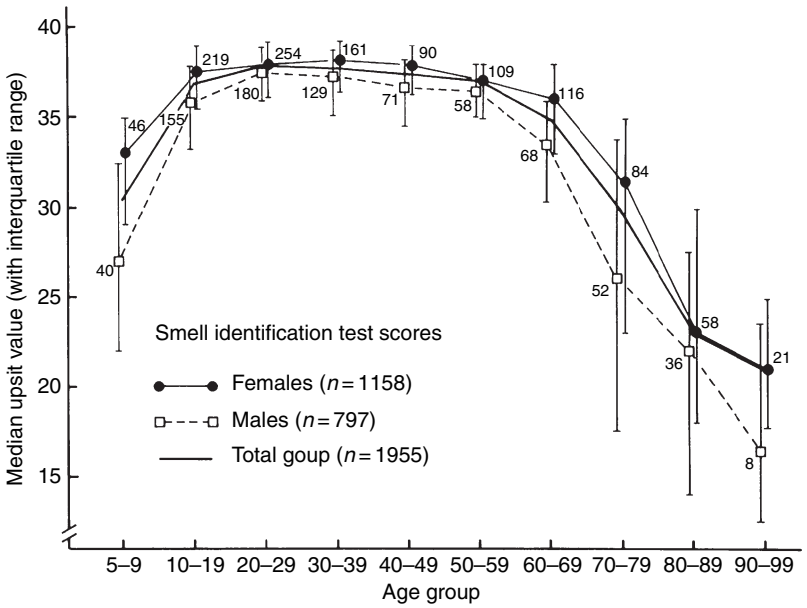

Figure 4 University of Pennsylvania smell identification test (UPSIT) scores as a function of age and gender. Numbers by data points indicate sample sizes modified from Doty, R. L., Shaman, P., Applebaum, S. L., Giberson, R., Siksorski, L., Rosenberg, *et al.* 1984a. Smell identification ability: changes with age. Science 226, 1441–1443; Doty, R. L., Shaman, P. and Dann, M. 1984b. Development of the University of Pennsylvania smell identification test: a standardized microencapsulated test of olfactory function. Physiol. Behav. 32, 489–502.

receptors (e.g., secondary to polyposis and excessive nasal engorgement), (2) damage to the olfactory membrane proper (e.g., from URIs, toxic chemical exposure, and occlusion of foramina through which the olfactory fila project), (3) damage to central nervous system (CNS) structures involved in olfactory transduction/processing (e.g., from strokes, epilepsy, and so on), and (4) systemic disturbances of metabolism or transduction (e.g., due to medications, hypothyroidism, diabetes, and liver or kidney disease). Approximately two-thirds of cases of chronic anosmia or hyposmia are due to prior URIs, rhinosinusitis, or head trauma (Deems, D. S. *et al.*, 1991). Mechanisms for the alteration of taste include (1) blockage of stimulus access to the taste buds (e.g., from damage to taste pores from caustic agents or burns, chronic lack of salivary proteins critical for taste bud maintenance), (2) the release of bad-tasting materials from dental appliances (e.g., bacterial infections, gingivitis, and purulent sialadenitis), (3) damage to one or more neural pathways or central brain regions (e.g., from epilepsy, tumors, strokes, viruses, occlusion of foramina through which nerves pass, and trauma), and (4) systemic disturbances of metabolism (e.g., medications, hypothyroidism, diabetes, and liver or kidney disease). Avitaminosis, particularly of the B group and C group, can result in pellagra, sprue, pernicious anemia, scurvy, or glossitis. Additionally, zinc and copper deficiencies are reportedly linked to taste disturbances (Mattes, R. D., 1995).

4.46.5.1 Upper Respiratory and Oral Infections

The most frequent cause of permanent smell loss in the adult human is an URI, such as associated with the common cold, influenza, pneumonia, or HIV+ (Deems, D. S. *et al.*, 1991). Often the respiratory illness is described as being more severe than usual, and in many cases dysosmia or phantosmia is present, at least initially. Most dysosmias subside over time, although some patients are left with a noticeable olfactory deficit. Such losses are most common in middle or older age, presumably reflecting cumulative insult and the challenge of epithelial regeneration in the face of reductions in the proliferation of basal cells and immature neurons. Evidence of damage to the olfactory epithelia from patients with post-URI anosmia includes extensive cicatrization, decreases in receptor cell number, absent or decreased numbers of cilia on remaining receptor cells, and replacement of sensory epithelium with respiratory-like epithelium (Yamagishi, M. *et al.*, 1994).

The taste system is similarly susceptible to damage from bacteria, viruses, and other agents. Some cases of Bell's palsy, for example, reflect viral damage to the facial nerve (e.g., from *Herpes simplex* virus-1), producing unilateral facial weakness, gustatory loss, and in some cases damage to the taste-salivary reflex, which is dependent upon a relay from the nucleus of the solitary tract to the parasympathetic fibers innervating the salivary glands (Murakami, S. *et al.*, 1996). Involvement of taste in Bell's palsy, which may involve over half the cases, localizes the lesion to the neural pathways from the pons, along the nervus intermedius portion of the facial nerve, through the geniculate ganglion, to the point where the chorda tympani joins the facial nerve in the facial canal. A more severe form of Bell's palsy, Ramsy–Hunt syndrome, results from an active *Herpes* infection of the geniculate ganglion and involves pain and vesicles in the external auditory canal or soft palate. Interestingly, dental procedures can activate viruses that, in turn, lead to infections that sometimes influence olfactory function.

4.46.5.2 Allergies and Rhinosinusitis

A significant number of patients with allergic rhinitis exhibit greater olfactory dysfunction than their nonallergic counterparts. In one study, for example, 23.1% of those with allergic rhinitis had a threshold at or above the 2½ percentile of the controls. The smell loss was associated with clinical or radiographic evidence of rhinosinusitis or nasal polyps. Thus, hyposmia was present in 42.9% of those with associated rhinosinusitis. The presence of hyposmia was only 14.3% in those with no associated rhinosinusitis (Cowart, B. J. *et al.*, 1993).

In general, olfactory dysfunction is related to the severity of rhinosinusitis [e.g., in one study, the mean UPSIT scores were 35, 31, 26, and 23 for Kennedy stages I to IV of the disease, respectively (Downey, L. L. *et al.*, 1996)]. While the smell loss associated with rhinosinusitis has been traditionally viewed as conductive (Figure 1), at best only weak associations have been found between quantitative olfactory test scores and measures of nasal airway patency (Cowart, B. J. *et al.*, 1993). Moreover, medical (e.g., administration of topical or systemic steroids) or surgical (e.g., excision of polyps) treatments rarely return olfactory function to normal, suggesting that the severity of histopathological changes within the olfactory mucosa may be the defining factor. Support for this hypothesis comes from

evidence that degree of epithelial inflammation is related to olfactory test scores in patients with chronic rhinosinusitis (Kern, R. C., 2000), and that olfactory epithelial biopsies from patients with nasal disease are less likely to yield olfactory-related tissue than those from controls (Feron, F. *et al.*, 1998). The same is true for anosmic vs. nonanosmic rhinosinusitis patients, the former of whom typically exhibit a more pathological epithelium (e.g., disordered arrangement of cells and more islands of respiratory-like epithelium) (Lee, S. H. *et al.*, 2000). While the taste system, per se, is not directly influenced by rhinosinusitis, unpleasant tasting discharge, e.g., from postnasal drip, is often present that is of significant concern to the patient.

4.46.5.3 Disorders Influencing Airway Patency

In addition to rhinosinusitis, other conditions that block or otherwise hinder airflow to the olfactory receptors can adversely influence the ability to smell. Children with choanal atresia, for example, suffer from smell loss. In this congenital disorder, the airway is obstructed by membranous or bony tissue. The limited data suggest that permanent olfactory dysfunction may occur in such patients, presumably reflecting the need for early exposure to odorants for normal olfactory system development. Thus, in one study, smell was tested before and after such repair in patients of relatively advanced age (8–31 years). Although one patient who had suffered from unilateral atresia had normal smell function, three others who had suffered from bilateral atresia had permanent olfactory loss (Gross-Isseroff, R. *et al.*, 1989). A reversible smell loss occurs in children whose nasal airflow is compromised by hypertrophied adenoid tissue (Figure 5) (Ghorbanian, S. N. *et al.*, 1983).

4.46.5.4 Head Trauma

Head trauma likely accounts for 10–20% of all smell and taste disorders (Deems, D. S. *et al.*, 1991). While there are studies that suggest between 4 and 7% of head trauma patients lose their sense of smell, incidence rates as high as 60% in cases of severe head injury have been reported. However, such high incidences are usually found in centers specializing in chemosensory disturbances and therefore are influenced by referral patterns (Doty, R. L. *et al.*, 1997c; Ogawa, T. and Rutka, J., 1999). In general, taste dysfunction resulting from trauma is much less common than posttraumatic smell dysfunction, with solitary ageusia of one or more primary taste modalities, as measured by whole-mouth testing, occurring in less than 1% of persons with major head injury (Deems, D. S. *et al.*, 1991). Only rarely are trauma-related taste disturbances unaccompanied by smell impairment.

A number of mechanisms have been implicated in trauma-related smell impairment, including (1) shearing injury to the olfactory nerve filaments of the cribriform plate as a result of brain movement relative to the skull, (2) damage to the nasal and sinus

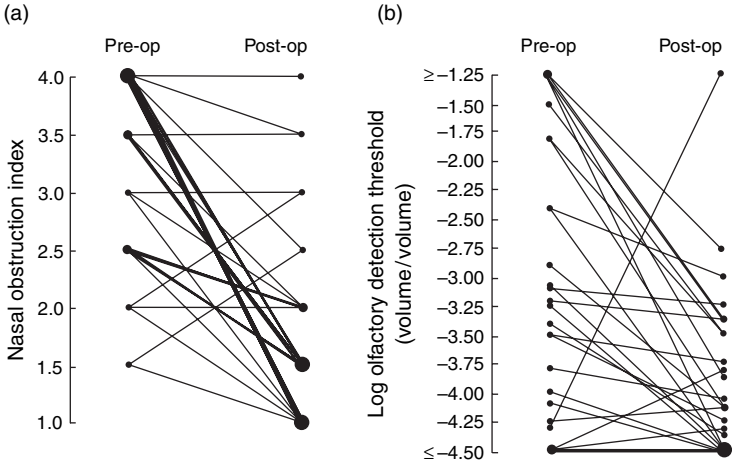

Figure 5 Nasal obstruction index (A) and olfactory detection threshold for phenyl ethyl alcohol (B) in 28 children before and after adenoidectomy. Each line joins preoperative (pre-op) and postoperative (post-op) values for an individual subject. Heavy lines denote confluence of several subjects who had the same preoperative and postoperative values (from Ghorbanian, S. N., Paradise, J. L., Doty, R. L. 1983. Odor perception in children in relation to nasal obstruction. Pediatrics 72, 510–516). Copyright © 1983 by the American Academy of Pediatrics.

architecture – with subsequent alteration of nasal airflow – without specific injury to the olfactory epithelium or neural projections, and (3) contusion or hemorrhage to central regions that mediate olfactory information (e.g., olfactory bulbs and tracts themselves, septal nuclei of the inferior frontal region, orbitofrontal territories, or the anteromedial temporal lobes). In addition to the severity of injury and loss of consciousness, there appear to be other factors associated with increased risk of developing anosmia after head trauma, including (1) anterior skull base fractures, (2) bilateral subfrontal lobe injury, (3) dural lacerations, and (4) cerebrospinal fluid leakage (Giasson, B. I. *et al.*, 2002). Occipital and lateral blows are more likely to result in anosmia than blows to the front of the head (Doty, R. L. *et al.*, 1997a; 1997b; 1997c). Compound fractures in the occipital, frontal, skull base, and mid-face are reported to be twice as likely as temporal and parietal fractures to result in olfactory alterations (Ogawa, T. and Rutka, J., 1999). In terms of facial fractures, nasozygomatic Le Fort fractures, fronto-orbital fractures, and pure La Fort fractures appear to most likely to be associated with smell disturbances (Horiguchi, T. *et al.*, 2003).

A strong correlate of head trauma-related anosmia is the severity of the injury (Doty, R. L. *et al.*, 1997a; 1997b; 1997c). Lower Glasgow coma scale ratings (GCS 3–8) are associated with a greater than 50% increase in the development of anosmia compared to moderate ratings (GCS 9–12) (Giasson, B. I. and Mushynski, W. E., 1996). Trauma-related loss of consciousness lasting 24 h or longer results in significantly more loss than that found in patients who have no loss of consciousness (Doty, R. L. *et al.*, 1997a; 1997b; 1997c).

The prognosis for posttraumatic ageusia is much better than for posttraumatic anosmia, and recovery from ageusia usually occurs in most patients over a period of a few weeks to months. The etiology of posttraumatic taste dysfunction varies. Head trauma that results in injury to the middle ear, a finding often encountered with temporal bone fractures, can result in both ipsilateral impairment of taste function and injury to the preganglionic parasympathetic fibers, thus preventing salivary secretion. Seven to 10% of temporal bone fractures reportedly result in facial nerve dysfunction (see Chang, C. Y. J. and Cass, S. P. 1999, for review). The lingual nerve, a branch of the mandibular division of the trigeminal nerve that subserves general somatic sensation and taste (due to coexisting chorda tympani fibers), can be damaged from trauma in and around the mouth and tongue, resulting in numbness and taste loss over the anterior tongue ispilateral to the side of injury. Trauma can produce Vernet's syndrome – a syndrome consisting of loss of taste in posterior third of tongue, paralysis of the vocal cord, palate, pharynx, trapezius, and sternocleidomastoid muscles secondary to lesions of the jugular foramen that affect CNs IX, X, and XI.

Isolated damage to the auriculotemporal nerve (ATN) can produce posttraumatic gustatory neuralgia, a taste-initiated, episodic, paroxysmal lancinating facial pain (often electric shock-like) in the cutaneous distribution of this nerve (Scrivani, S. J. *et al.*, 1998). Posttraumatic abnormalities involving the ATN, such as sweating and flushing following a taste stimulus, are termed Frey's syndrome. Although typically provoked by tastants, this syndrome can be elicited in some cases by the smell of food or emotional excitement (Scrivani, S. J. *et al.*, 1998).

4.46.5.5 Iatrogenesis

Head trauma is not the only type of trauma that can influence chemosensory function. In the case of olfaction, for example, various nasal and other surgical operations have been associated with smell loss (e.g., anterior ethmoidectomy, posterior ethmoidectomy, polypectomy, middle turbinate medialization, uncinectomy, sphenoidectomy, and anterior craniotomy). Although there are scattered reports of adverse influences of septoplasty and rhinoplasty on olfactory function, these operations only rarely influence smell function.

Trauma-related damage to the glossopharyngeal nerve, a nerve which is relatively well protected in comparison with the facial nerve, can occur from tonsillectomy, bronchoscopy, or laryngoscopy, reflecting the proximity of the lingual branch of this nerve to the muscle layer of the palatine tonsillar bed (Arnhold-Schneider, M. and Bernemann, D., 1987). Damage to this nerve is usually accompanied by damage to the nearby vagus, accessory, or hypoglossal nerves. Vernet's syndrome can also arise after parotid gland surgery, temporomandibular joint (TMJ) surgery, carotid endarterectomy, orthognathic surgery, and oncologic surgery.

4.46.5.6 Tumors and Central Nervous System Lesions

Damage to the olfactory bulbs and tracts can occur from numerous central tumors, including

meningiomas from the dura of the cribriform plate and surrounding regions (e.g., olfactory groove meningiomas, suprasellar ridge meningiomas), pituitary growths that extend above the sella turcica, and tumors within or around the third ventricle (for review, see Kern, R. C. and Mathog, R. H., 1991). Hyposmia or anosmia can be the principal or sole feature of an olfactory groove neoplasm. Unilateral and bilateral olfactory loss has been reported in frontal lobe glioma, suprasellar meningioma, and sphenoidal ridge meningioma, as well as in non-neoplastic space filling lesions, such as aneurysms of the anterior communicating bifurcation, large internal carotid aneurysms extending over the pituitary fossa, and hydrocephalus that forces the floor of the third ventricle downward (Graff-Radford, N. R. *et al.*, 1997). Removal of anterior skull base tumors via classical bifrontal craniotomy is commonly associated with postoperative anosmia and other complications (Jung, T. M. *et al.*, 1997).

Tumors growing anywhere along the path of the facial nerve – from the oral cavity, through the skull base, temporal bone and middle ear, to the cerebellopontine angle and the brainstem – can cause a mononeuropathy of the nerve and alterations in taste function. Nearly 10% of patients with surgically confirmed acoustic neuromas experience loss of taste as a primary complaint (Harner, S. G. and Laws, E. R., Jr., 1981). Lesions to brainstem structures that subserve taste can produce dysgeusia, although usually not without significant impairment of other cranial nerves or long tracts. Notable brainstem areas involved in taste that are susceptible to CNS lesions include the tractus solitarius and its nucleus (where injury produces ipsilateral deficits) and the pontine tegmentum (where injury produces bilateral deficits). Bilateral injury to the thalamus can result in ageusia, although unilateral lesions above the brainstem do not usually cause complete loss of function (likely due to the multiple areas involved in processing taste information). An isolated unilateral lesion to the thalamus or the parietal lobe may cause contralateral taste disturbance.

Gustatory perception may also be affected by cortical injury to areas of association cortex outside of the main gustatory processing regions. In a manner similar to that seen in the visual, auditory, tactile, and olfactory sensory systems, left unilateral neglect of taste sensations can result from contralateral injury to the right hemisphere (e.g., parietal lobe, thalamus, basal ganglia) (Bellas, D. N. *et al.*, 1988). In fact, a specific syndrome of buccal hemineglect exists in which patients neglect mouth and food products in the left half of the mouth and fail to initiate chewing and swallowing when food is in this location (Andre, J. M. *et al.*, 2000). This syndrome can result in choking or a socially embarrassing tendency to drool and regurgitate unnoticed food.

In a review of 15 reported cases, Onoda, K. and Ikeda, M. (1999) found that unilateral impairment of taste function occurs with injury to any one of several central locations, including the pons (eight cases), the thalamus (five cases), the midbrain (one case), and the internal capsule (one case). Based on the side of the respective central lesion and its effect on either unilateral or contralateral gustatory function, these authors surmised that the gustatory pathways ascend ipsilaterally from the medulla, cross over in their course from the pons to the midbrain, and synapse within the contralateral thalamus. Nonetheless, unilateral taste stimulation can reportedly evoke contralateral and bilateral cortical electrical responses (Kida, A., 1974), and one study suggests that taste information from both sides of the tongue must pass through the left insula for proper recognition to occur (Pritchard, T. C. *et al.*, 1999). In this study of six stroke patients with unilateral lesions of the insular cortex and three patients with brain damage outside the insula, damage to the right insula caused ipsilateral taste deficits in recognition and intensity, whereas damage to the left insula caused an ipsilateral deficit in taste intensity but a bilateral deficit in taste recognition.

Before the advent of modern imaging, olfactory tests were used to help diagnose and localize cribriform plate meningiomas and other tumors impacting the olfactory nerve (Elsberg, C. A., 1935a; 1935b). Olfactory recognition thresholds were reported to be elevated on the side where pressure was exerted on one olfactory nerve. When both nerves were involved, thresholds were bilaterally elevated, with more dysfunction on the most affected side. Expanding lesions on the ventral surfaces of the frontal cerebral lobes, as well as for suprasellar meningiomas and aneurysms of the internal carotid artery or the anterior part Willis' circle, produced such changes. Thresholds were uninfluenced by pituitary adenomas confined to the sella turcica, but were heightened if growth occurred above this bony structure. Tumors in or near the midline of the cranial cavity produced long-lasting adaptation (e.g., tumors of the corpus callosum, parasagital meningiomas, and infiltrating growths extending to the medial surface of a cerebral hemisphere). Decreased recognition threshold sensitivity sometimes is accompanied by generalized increased intracranial pressure

(Elsberg, C. A., 1935b). However, the findings of a recent study of ten patients with tumors localized to the left or right temporal or frontal lobes differed somewhat from these results (Daniels, C. *et al.*, 2001). Thus, patients with right-side tumors had odor discrimination deficits on both the left and the right. Those with left-side tumors exhibited attenuated function only when the odorant was presented to the left side, in accord with the notion that right hemisphere is more involved in olfactory processing than the left.

4.46.5.7 Drug Effects

Although both taste and smell can be altered by medications, drug-related taste disturbances occur much more frequently than drug-related olfactory disturbances. Over 250 medications reportedly alter the sense of taste, including antiproliferative drugs, antirheumatic drugs, antibiotic drugs, psychotrophic drugs, and drugs with sulfhydryl groups, such as penicillamine and captopril (Doty, R. L. and Bromley, S. M., 2004). Antihypertensive and antihyperlipidemic drugs, including ACE inhibitors, are commonly associated with taste disturbances, including hypogeusia and dysgeusia (Ackerman, B. H. and Kasbekar, N., 1997; Doty, R. L. *et al.*, 2003). Terbinafine, a commonly used antifungal medication, has been linked to taste disturbance that reportedly can last many months and, in some cases, for years (Doty, R. L. and Haxel, B. R. 2005). Among the medications used in the treatment of HIV and AIDS, the protease inhibitors have a taste themselves and appear to adversely modify the taste perception of other taste compounds (Schiffman, S. S. *et al.*, 1999). In a study of six psychotropic medications, including amytriptyline, clomipramine, desimpramine, imipramine, doxepin, and trifluoperazine, Schiffman, S. S. *et al.* (1998) found that these drugs do not only have a taste of their own, but alter the intensity of other tastants (such as salt and sugar).

Medication-related chemosensory changes can, in some instances, be reversed by discontinuance of the offending drug, by employing alternative medications, or by changing drug dosage. Unfortunately, many pharmacological agents appear to induce long-term alterations in taste that may take months to disappear even after drug discontinuance. Although the Physicians' Desk Reference (PDR) (2005) can be helpful in identifying medications that may result in drug-related chemosensory dysfunction, there is lack of uniformity and control in the acquisition of this information, and the relative influences on taste and smell can be confused.

4.46.5.8 Congenital and Inherited Disorders

The vast majority of idiopathic cases of apparent congenital anosmia exhibit agenesis or dysgenesis of the olfactory bulbs and stalks (Yousem, D. M. *et al.*, 1996). Several congenital olfactory syndromes are accompanied by endocrine dysfunction (e.g., Kallmann's syndrome), as discussed in the Section 4.46.5.9. Although most idiopathic congenital cases are presumably inherited, some may reflect early viral- or trauma-induced insults to the olfactory epithelium that produce regression of olfactory bulb/tract volume over time. Lygonis, C. S. (1969) reported total anosmia (without any apparent associated disorders) in members of four generations of a family living in an isolated island community and suggested that the pattern of inheritance was likely autosomal dominant. Singh, N., *et al.* (1970) described a familial anosmia loosely associated with premature baldness and vascular headaches, which appeared to be inherited as dominant with varying penetrance.

Recently, smell dysfunction has been reported in Bardet–Biedl syndrome (BBS), a rare pleiotropic genetic disorder associated with, among other things, retinal degeneration, obesity, limb anomalies, genitourinary abnormalities, and cognitive impairment (Iannaconne, A. *et al.*, 2005). Eight BBS genes have been cloned. One of these genes, the BBS4 gene, has been found in the olfactory neuroepithelium and plays a significant role in ciliary physiology. Interestingly, BBS4-knockout mice exhibit smell loss (Iannaconne, A. *et al.*, 2005).

Familial dysautononia (Riley–Day syndrome) is an autosomal recessively inherited disease with sensory neuropathy that mostly affects Ashkenazi Jewish patients. This disorder is associated with defective autonomic control, insensitivity to pain, hyporeflexia, and impaired lacrimation. Most notably for our purposes, patients with familial dysautonomia exhibit taste impairment secondary to the lack of fungiform papillae and lingual taste buds (Gadoth, N. *et al*, 1997). Taste dysfunction secondary to the absence of these structures was also described in two Japanese siblings who had late-onset progressive ataxia, global thermoanalgesia, sensorineural deafness, and mild autonomic disturbances (Fukutake, T. *et al*, 1996). This particular disease entity may represent a variant of late-onset hereditary spinocerebellar degeneration. More recently, Uchiyama, T. *et al.* (2001) described an individual with an apparently new variant of Machado–Joseph disease that lacked fungiform papillae.

4.46.5.9 Endocrine and Metabolic Diseases

A number of endocrine disorders have been associated with smell dysfunction. In general, the mechanisms responsible for the smell loss – aside from obvious anatomical alterations in the primary olfactory pathways – are poorly understood.

4.46.5.9.1 Addison's disease

One study has reported that patients with untreated adrenocortical insufficiency exhibit hypersensitivity to several odorants (e.g., pyridine, thiophene, and nitrobenzene), as well as to the vapors above aqueous solutions of six tastants (NaCl, KCl, HCl, $NaHCO_3$, sucrose, and urea) (Henkin, R. I. and Bartter, F. C. 1966). No overlap of the distribution of scores from the patient and control groups was observed, which is a remarkable finding. The patients detected differences between water and the tastant vapors at 1/10 000 the concentration of that observed for normals. The increased sensitivity was not influenced by daily 20 mg injections of deoxycorticosterone acetate (DOCA) for periods up to 10 days. In contrast, a similar regimen of 20 mg of the carbohydrate-active steroid prednisolone returned sensitivity to normal within 24 h.

Unfortunately, no attempts have been made to replicate this early work using more sophisticated sensory testing. If valid, the effects may reflect general processes, as hypersensitivity was also noted for pure-tone auditory thresholds and filtered and nonfiltered speech discrimination tests (Henkin, R. I. and Daly, R. L., 1968).

4.46.5.9.2 Cushing's syndrome

Cushing's syndrome is characterized by hypercortisolism, a chronic excessive secretion of adrenal corticosteroids. Adrenocorticotropic hormone (ACTH) hypersecretion occurs in approximately 80% of cases; the remaining approximately 20% reflect ACTH-independent etiologies (e.g., cortisol-secreting tumors or adrenal gland adenomas and carcinomas) (Ferrante, M. A., 1999). According to Henkin R. I. (1975), these patients have decreased sensitivity to odors, tastes, and sounds. In accord with this notion is a report by Ezeh P. I. *et al.* (1992) that dogs given chronic dexamethasone exhibit increased detection thresholds for benzaldehyde and eugenol (Ezeh, P. I. *et al.*, 1992).

4.46.5.9.3 Diabetes

A number of studies suggest that both taste and smell functions are altered by diabetes (for review, see Settle, R. G., 1991). In the case of smell, both threshold and suprathreshold deficits have been observed. One study found a correlation between smell identification scores and macrovascular disease in such patients (Weinstock, R. S. *et al.*, 1993). A progressive loss of taste beginning with glucose and extending to other sweeteners, salty stimuli, and then all stimuli has been noted (Hardy, S. L. *et al.*, 1981). In newly diagnosed noninsulin-dependent diabetics, quantifiable taste impairment exists that may be reversible, to some degree, with correction of the hyperglycemia (Perros, P. *et al.*, 1996). A subgroup of approximately 10% of first-degree relatives of noninsulin-dependent diabetics that have no neuropathies evidence taste dysfunction specific to glucose, but not other sugars such as fructose (Settle, R. G., 1981). It is not known if these individuals are the ones who go on to later develop diabetes, but this would seem quite possible.

4.46.5.9.4 Hypothyroidism

One might expect hypothyroidism to influence taste and smell functions, since this disease produces alterations in other sensory systems. Thus, 36–83% of hypothyroid patients are said to experience somesthetic disturbances, and 25–45% auditory or visual dysfunction, with night blindness reportedly being a common feature of the disorder (Mattes, R. D. *et al.*, 1986). In fact, dysgeusias appear to be disproportionately represented in hypothyroid patients (Deems, D. S. *et al.*, 1991). McConnell, R. J. *et al.* (1975) reported that seven of 18 patients with untreated primary hypothyroidism (39%) were cognizant of some alteration in their sense of smell, with three (17%) experiencing dysosmia. Lewitt M. S. *et al.* (1989) noted that 11 of 16 (69%) hypothyroid patients complained of alterations in taste and smell, although no detection threshold differences between the patients and controls were found for the odorant phenyl ethyl alcohol. Pittman J. A. and Beschi R. J. (1967) reported no influences of hypothyroidism on taste thresholds. Although experimentally induced hypothyroidism in rats fails to alter detection sensitivity to either tastes or odors, taste preferences are significantly effected, suggesting that thyroid disease may influence qualitative sensations, rather than sensitivity, per se (Brosvic, G. M. *et al.*, 1996).

4.46.5.9.5 Kallmann's syndrome

Kallmann's syndrome, which is more prevalent in men than in women, is defined as anosmia accompanied by idiopathic hypogonadotrophic hypogonadism (IHH).

This autosomal dominant disorder has incomplete expressivity and can be accompanied by cryptorchidism, deafness, midline craniofacial abnormalities, tooth agenesis, and renal anomalies. Relatives may be normal, may have anosmia unaccompanied by gonadal dysfunction, or may have anosmia and hypogonadism. Kallmann's syndrome patients typically have bilateral agenesis or dysgenesis of the olfactory bulbs and tracts, although lateralized variability may be present (Yousem, D. M. *et al.*, 1993).

The anosmia of Kallmann's syndrome is not reversed by either gonadotropin or gonadal steroid therapy, reflecting its anatomical basis. Given that testicular derangement can be largely reversed by hormones when given at the appropriate time, it is important to detect the endocrine problem as early as possible to prevent the possible development of irreversible atrophic changes and to minimize social consequences. Unfortunately, routine pediatric examinations do not test for olfactory function, and many individuals lacking such function, particularly children, do not seek help for this difficulty.

4.46.5.9.6 Kidney disease

Chronic renal failure is associated with alterations in smell and taste function, and in some circumstances, transplantation may improve the function. For example, Griep, M. I. *et al.* (1997) determined amyl acetate detection thresholds on 101 patients with chronic renal failure. Patients with cognitive deficits were excluded from analysis. No differences were noted for patients on peritoneal and hemodialysis, or for a subgroup of patients tested before and after hemodialysis. However, transplanted patients had better odor perception relative to matched dialysis controls. Significant negative correlations were noted between threshold sensitivity and serum concentrations of urea and phosphorus, as well as between such sensitivity and protein catabolic rates.

In patients younger than 55 years with uremia, a significant impairment of taste recognition was reported for salty, sweet, bitter, and sour agents relative to controls (Ciechanover, M. *et al.*, 1980). This impairment for sour and bitter, however, was found to show improvement immediately after dialysis. These uremic patients reportedly showed no signs of zinc deficiency.

4.46.5.9.7 Pseudohypoparathyroidism

Pseudohypoparathyroidism (PHP) is characterized by deficient responsiveness to, but not deficient production of, parathyroid hormone. Type Ia PHP exhibits generalized hormone resistance, a deficiency of the alpha chain of the stimulatory guanine nucleotide-binding protein ($G_s\alpha$) of adenylyl cyclase, and a constellation of developmental and skeletal anomalies termed Albright hereditary osteodystrophy (AHO). Type Ia patients exhibit obesity, short stature, brachydactyly, round faces, and subcutaneous ossifications. In contrast, type Ib patients have a specific hormone resistance to parathyroid hormone and lack a deficiency in $G_s\alpha$ protein activity. They also do not have AHO.

Patients with type Ia PHP, but not type Ib PHP, were reported, in the 1980s, to have olfactory dysfunction (Weinstock, R. S. *et al.*, 1986). The problem was attributed to the $G_s\alpha$ protein deficiency, since G_s proteins are involved in the first stages of olfactory transduction (Weinstock, R. S. *et al.*, 1986). More recent work, however, found type 1b patients to have similar olfactory dysfunction, making it unlikely that the PHP-related deficit reflects a $G_s\alpha$ protein deficiency (Doty, R. L. *et al.*, 1997a). In this same study, patients with pseudopseudohypoparathyroidism (PPHP), a disorder found in some relatives of patients with type Ia PHP, were found to have relatively normal smell function. Like type Ia PHP, PPHP is accompanied by a $G_s\alpha$ protein deficiency and by AHO, but not by a generalized end-organ hormone insensitivity. These findings suggest that the smell loss of PHP type Ia patients is unlikely due to $G_s\alpha$ deficiency. More work is clearly needed to determine the basis of the olfactory deficits in some patients with PHP.

4.46.5.9.8 Turner's syndrome

Chromatin-negative gonadal dysgenesis (Turner's syndrome) results from a X-chromosomal monosomy (i.e., 45,X karyotype). This disorder is characterized by a feminized phenotype, a short and sometimes webbed neck, small stature, low-set ears, a high-arched palate, shield-like chest, and sexual infantilism. Congenital lymphedema, cardiac deficits, and renal deficits are also sometimes found. Such patients reportedly have elevated detection and recognition thresholds to pyridine, thiophene, and nitrobenzene (Henkin, R. I., 1967). Gonadal hormone therapy was found to reverse the chemosensory deficits. A genetic basis for the chemosensory disorder is suggested by the fact that the mothers of the patients exhibited similar olfactory abnormalities.

4.46.5.10 Psychiatric Disorders

Several psychiatric disorders are associated with altered chemosensation. Such disorders include severe

stage anorexia nervosa, alcoholism with or without Wernicke–Korsakoff syndrome, seasonal affective disorder (SAD), attention-deficit/hyperactivity disorder (ADHD), depression, olfactory reference syndrome (ORS), schizophrenia, and chronic hallucinatory psychoses.

4.46.5.10.1 Alcoholism

Olfactory function is depressed in chronic alcoholics, particularly those whose alcoholism has led to vitamin deficiencies and the Wernicke–Korsakoff syndrome (Mair, R. G. *et al.*, 1986). For example, DiTraglia, G. M. *et al.* (1991) found alcoholics to have lower UPSIT scores than nonalcoholic controls; thus, 32% of 37 alcoholics exhibited scores within the clinically impaired range, as compared with 5% of 21 controls. A significant correlation was found between UPSIT scores and cortical sulcal volumes. In a follow-up study of 23 alcoholic subjects, those who had remained abstinent ($n = 15$) had significantly higher UPSIT scores than those who had not ($n = 8$). Subsequent studies by this group found impairment on the UPSIT to be associated with elevated cortical and ventricular CSF volumes, as well as with reduced cortical and subcortical gray matter volumes (Shear, P. K. *et al.*, 1992). Moreover, thalamic volume was found to be a significant unique predictor of UPSIT scores.

4.46.5.10.2 Anorexia and bulimia nervosa

Anorexia is associated with loss of olfactory function. Fedoroff, I. C. *et al.* (1995) administered the UPSIT and the phenyl ethyl alcohol threshold test to 55 eating-disordered hospitalized women. Very low-weight anorexics ($n = 11$) exhibited statistically significant deficits, although the magnitude of the losses was relative small, being approximately 3 UPSIT points and approximately 1.25 log vol/vol dilution units. The problem remained even after considerable weight has been regained at the time of discharge (although ideal body weight had not yet been achieved), suggesting the possibility that the effect may be long lasting.

4.46.5.10.3 Attention-deficit/hyperactivity disorder

Olfactory dysfunction has been associated with some forms of ADHDs. For example, Gansler, D. A. *et al.* (1998) found that patients diagnosed with ADHD/inattentive type (ADHD–) exhibited, among other things, odor identification deficits and deficits on a test of working memory, whereas those diagnosed with ADHD/hyperactive impulsive type (ADHD+) exhibited relatively more dysfunction on the Wisconsin card sorting test. These authors suggested that such differences may be linked to dysregulation of separate frontal neurotransmitter systems and/or brain regions.

4.46.5.10.4 Depression

Although persons with olfactory dysfunction often are depressed, the reverse is rarely true (i.e., depression does not cause smell loss). Thus, Amsterdam, J. D. *et al.* (1987) administered the UPSIT to 51 unmediated patients with well-documented moderate-to-severe depression and to 51 age-, race-, and gender-matched controls. No differences were observed between the scores of the two groups, a finding that has been replicated by others using this same test (Kopala, L. C. *et al.*, 1994).

Electrogustometric thresholds do not differ between depressed and nondepressed subjects (Scinska, A. *et al.*, 2004). Nevertheless, clinically depressed patients sometimes complain of an unpleasant or diminished taste that is not readily explainable by medications or other causes (Miller, S. M. and Naylor, G. J., 1989). Paradoxically, pleasantness ratings are higher in depressed patients than in controls for high concentrations of sucrose (Amsterdam, J. D. *et al.*, 1987; Kavaliers, M., 1989).

4.46.5.10.5 Olfactory reference syndrome

Patients with ORS believe that unpleasant or unhealthy smells emanate from their body (intrinsic hallucinations) or from some external source (extrinsic hallucinations). In cases where the hallucinations are minimal, patients complain about the odor but do not take steps to remove it. In other cases, the odor is so problematic that reasonable steps are taken to eliminate the odor (e.g., complaining to authorities or plugging up the chimney with newspapers). Compulsive washing behavior, changing clothes, and restriction of social activity is common in intrinsic hallucinatory cases. Some cases of ORC seem closely linked with an obsessive compulsive disorder and are amenable to treatment with serotonin uptake inhibitors (Dominguez, R. A. and Puig, A., 1997). ORS is generally viewed as distinct from schizophrenic or affective disorders (Pryse-Phillips, W., 1971; Bishop, E. R. 1980).

4.46.5.10.6 Seasonal affective disorder

There is some suggestion that SAD is associated with enhanced olfactory sensitivity. Thus, lower detection thresholds for the odorant phenyl ethyl alcohol have been reported in such patients relative to controls

(Postolache, T. T. *et al.*, 2002). This effect occurred regardless of whether the testing was done in the summer and winter, and no evidence of seasonal changes was found. However, a subsequent report, in which both UPSIT and threshold measures were determined for each side of the nose separately, found no differences between SAD patients and controls. Interestingly, however, depression scores were negatively correlated with right-, but not left-side UPSIT scores, suggesting the possibility of some laterality in affective state that influences smell function (Postolache, T. T. *et al.*, 1999).

4.46.5.10.7 Schizophrenia

Patients with schizophrenia exhibit moderate bilateral losses in olfactory function. In a comprehensive meta-analytic study, the median UPSIT score from 13 SZ studies was 32.5 (Moberg, P. J. *et al.*, 1999). The median effect size (i.e., the mean difference between patient and control groups expressed in SD units) for 17 SZ studies employing the UPSIT was 0.92. This deficit is clearly less, on average, than that seen in such neurodegenerative disorders as Alzheimer's disease (AD) and Parkinson's disease (PD) (see Section 4.46.5.11), where median effect sizes for eight AD and four PD studies have been reported as 2.01 and 1.66, respectively (Mesholam, R. I. *et al.*, 1998). In a recent study from our center, 23% of a group of 41 patients with SZ exhibited UPSIT scores indicative of microsmia or anosmia, in contrast to 94.4% of a group of 18 AD patients and 96.3% of a group of 54 PD patients (Moberg, P. J. *et al.*, unpublished data).

The olfactory decrement of SZ appears early in the disease process and, in fact, is found in many patients who may be prone to SZ, such as those with schizotypy or with family histories positive for significant mental illness (Park, S. and Schoppe, S., 1997; Kopala, L. C. *et al.*, 1998). This deficit appears to be more strongly related to neuropsychological measures of frontal lobe function (e.g., problems in executive function) than to measures of medial temporal lobe function (e.g., memory) (Pantelis, C. and Brewer, W. J., 1995); functional imaging studies report hypometabolism or decreased activation within the subtemporal and subfrontal lobes, particularly on the right (Buchsbaum, M. S. *et al.*, 1991). The olfactory bulbs and tracts are reduced in patients with SZ, as well as in their first-order relatives (Turetsky, B. I. *et al.*, 2003), although the significance of such reduction is not entirely clear. The smell loss of SZ correlates with negative, but not positive, symptoms of the disorder (Brewer, W. J. *et al.*, 1996). UPSIT scores are inversely and significantly correlated with disease duration, suggesting that some progression of pathology may be occurring somewhere in the olfactory pathways (Moberg, P. J. *et al.*, 1997). This phenomenon appears to be independent of medication history and gender. Presently, odor identification ability appears to be the only neuropsychological marker known to correlate with disease duration in SZ.

4.46.5.11 Neurodegenerative Diseases

The ability to smell is compromised in a number of neurodegenerative diseases, including AD, Down's syndrome (DS), Huntington's disease (HD), idiopathic PD, multi-infarct dementia (MID), multiple sclerosis (MS), Pick's disease, restless leg syndrome, and the parkinsonism–dementia complex of Guam (PDC) (for recent review, see Doty, R. L., 2003). The degree of olfactory dysfunction differs, on average, amongst most of these disorders. For example, as discussed in more detail below, AD, PD, and PDC are accompanied by marked alterations in the ability to smell, whereas HD and MID are accompanied by more moderate alterations. Essential tremor, progressive supranuclear palsy (PSP), and 1-methyl-4-phenyl-l,2,3,6-tetrahydropyridine-induced parkinsonism (MPTP-P) are associated with no, or only minor, changes in the ability to smell, in spite of the fact that they share major clinical features with PD.

4.46.5.11.1 Alzheimer's disease

The smell dysfunction of AD, although prevalent and marked (present in 85–90% of patients), is usually not total. Indeed, many patients are unaware of their disorder until after being tested ((Doty, R. L. *et al.*, 1987). The loss affects both nasal chambers in the earliest disease stages, including some cases of questionable AD, and appears to increase in magnitude with time. In a meta-analysis of 11 olfactory/AD studies, effect sizes ranging from 0.98 to 12.15 (median = 2.17) were noted (Mesholam, R. I. *et al.*, 1998). The olfactory dysfunction is reflected by decreased odor-related activation of central structures (e.g., subfrontal temporal lobe), as measured by positron emission tomography (PET; Figure 6) (Kareken, D. A. *et al.*, 2001).

Olfactory dysfunction – particularly in conjunction with other risk factors – appears to be a predictor of subsequent development of AD in older persons. For example, Graves, A. B. *et al.* (1999) administered a 12-item smell identification test to 1604 nondemented community-dwelling senior citizens 65 years of age or

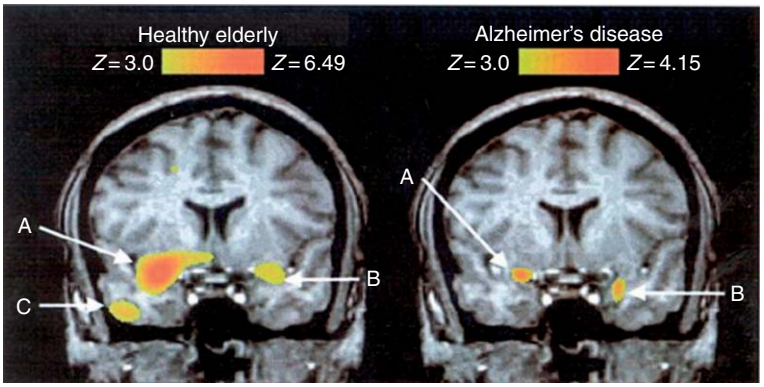

Figure 6 Left: Whole brain subtraction of olfactory stimulation minus control stimulation in healthy elderly control participants, coregistered on a T1-weighted reference magnetic resonance image ($n = 7$), accounting for one control participant whose right temporal lobe fell outside the scanner field of view. Right and left are reversed. Regions of interest are as follows: (a) Right frontotemporal junction (piriform area); (b) Left piriform area; (c) Right anterior-ventral temporal lobe (Brodmann 20). Right: Same whole-brain subtraction in patients with Alzheimer's disease. Regions of interest are as follows: A. 7 mm anterior to the frontotemporal junction (piriform) region in the control participants' image; B. Left amygdala-uncus (from Kareken, D. A., Doty, R. L., Moberg, P. J., Mosnik, D., Chen, S. H., Farlow, M. R., *et al*. 2001. Olfactory-evoked regional cerebral blood flow in Alzheimer's disease. Neuropsychology 15, 18–29). older. Over a subsequent 2 year time period, the identification test scores proved to be a better predictor of cognitive decline than global cognitive test scores. Anosmics who possessed at least one APOE-4 allele had 4.9 times the risk of having cognitive decline than normosmics not possessing this allele. This is in contrast to a 1.23 times greater risk for cognitive decline in normosmic individuals possessing at least one such APOE allele. Anosmic women who possessed at least one APOE-4 allele had an odds ratio of 9.71, compared to an odds ratio of 1.90 for women who were normosmic and possessed at least one allele. The corresponding odds ratios for men were 3.18 and 0.67, respectively. This study, along with similar longitudinal studies (e.g., Tabert, M. H. *et al*., 2005), strongly suggests that olfactory testing is a useful aid in determining those at-risk individuals who are most likely to develop AD.

4.46.5.11.2 Amyotrophic lateral sclerosis

Amyotrophic lateral sclerosis (ALS), traditionally viewed as a motor neuron disease, is associated with olfactory dysfunction. The degree of dysfunction is less than that seen in AD or PD, with average UPSIT scores falling around 30. One study of 58 patients with motor neuron disease reported that only bulbar patients exhibit significant deficits (Hawkes, C. H. *et al*., 1998). Another study of 37 ALS patients found that nearly half had UPSIT scores that fell within the normal range (Sajjadian, A. *et al*., 1994). Nonetheless, in the latter study, 75.7% of the patients scored below their individually matched controls. Only 11% of the ALS patients had total or near-total anosmia. Although no sex differences or laterality in the ALS-related test scores were observed, an age-related decrement was present. Interestingly, significant correlations were found between UPSIT scores and peripheral nerve conductance measures. One histological study of the olfactory bulbs from eight ALS patients revealed excessive lipofuscin deposition in all eight cases, suggesting subclinical neuronal damage (Hawkes, C. H. *et al*., 1998).

4.46.5.11.3 Multiple sclerosis

Although rare, smell loss can be a presenting symptom of MS (Constantinescu, C. S. *et al*., 1994). About a quarter of MS patients appear to exhibit olfactory dysfunction at any one time (Doty, R. L. *et al*., 1984b). The demyelinating plaques appear to be the basis of the disorder, as strong inverse correlations have been found between odor identification test scores and the number of plaques within the subfrontal and subtemporal lobes (Doty, R. L. *et al*., 1997b; Zorzon, M. *et al*., 2000). No such relationship is present in other brain regions. Longitudinal studies suggest that olfactory function waxes and wanes in relation to the exacerbation and remission of plaques within subtemporal and subfrontal lobes (Doty, R. L. *et al*., 1999). Evidence that MS alters taste function is limited,

although suprathreshold deficits have been observed for both tests of identification and perceived intensity (Catalanotto, F. A. *et al.*, 1984).

4.46.5.11.4 Parkinson's disease

Parkinson's disease, which is classically considered a motor disorder, is accompanied by smell loss with a prevalence rate greater than tremor, one of the cardinal signs of the disorder (Doty, R. L. *et al.*, 1988). As in AD, total anosmia is not the rule. Thus, only 38.3% of 81 patients evaluated in one study had UPSIT scores suggestive of anosmia, and only 13% of 38 patients who received an odor detection threshold test were unable to detect the highest odorant concentration presented (Doty, R. L. *et al.*, 1988). Moreover, all but one of 41 PD patients asked whether an odor was present on each of 40 UPSIT items answered affirmatively to 35 or more of the items, even though most were unable to identify the majority of the odors or felt that the perceived sensation did not correspond to the response alternatives. While olfactory loss is generally bilateral, there can be slight individual differences in the degree to which the left and right sides of the nose are involved. No association exists, however, between the side of relatively greater involvement and the side of hemiparkinsonism, as might be expected if asymmetrical damage to striatal dopamine systems were involved in the olfactory problem (Doty, R. L. *et al.*, 1992). The smell loss is unrelated to the magnitude of the motor symptoms, as well as a range of neuropsychological measures (Doty, R. L. *et al.*, 1989), although subtle variations among so-called benign vs. malignant forms may be present (Stern, M. B. *et al.*, 1994). Anti-PD medications (e.g., L-dopa, dopamine agonists, and anticholinergic compounds) have no influence on the smell deficit, which occurs as severely in nonmediated or nevermedicated patients as in medicated ones (Doty, R. L. *et al.*, 1992). A correlation between striatal dopamine transport activity, an index of the health of a neuron, and smell function has been recently reported (Siderowf, A. *et al.*, 2005).

The PD-related smell loss appears in both familial and sporadic forms and may be a sign of the preclinical disease state (Markopoulou, K. *et al.*, 1997; Berendse, H. W. B., 2001). As in the case with AD, some asymptomatic first-degree relatives of patients with either familial or sporadic forms of PD appear to exhibit olfactory dysfunction (Montgomery, E. B. *et al.*,. 1999). Recently, Berendse, H. W. B. (2001) administered tests of odor detection, identification, and discrimination to 250 relatives of PD patients (approximately 84% children, approximately 16% siblings, and one parent). In 25 hyposmic and 23 normosmic individuals sampled from this group, nigrostriatal dopaminergic function was assessed using single-photon emission computer tomography (SPECT) with [^{125}I]β-CIT as a dopamine transporter ligand. An abnormal reduction in striatal dopamine transporter binding was present in four of the 25 (16%) hyposmic relatives, two of whom subsequently developed clinical parkinsonism, and in none of the 23 normosmic relatives. Significant reductions in dopamine transporter binding were found only in hyposmic relatives of PD patients, suggesting olfactory dysfunction may precede clinical motor signs in PD. Such findings reiterate the point that olfactory testing, in conjunction with other measures, is likely useful in the early detection of PD.

Although the basis of the PD-related olfactory loss has been debated, Braak *et al.* present anatomical evidence suggesting that first CNS lesions of PD develop simultaneously within (a) the olfactory bulb and related portions of the AON and (b) the dorsal motor nucleus of the vagus nerve and adjoining intermediate reticular zone (Figure 7) (Del Tredici, K. *et al.*, 2002; Braak, H. *et al.*, 2003b). Cell types that succumb to PD-related development of inclusion bodies are primarily unmyelinated or poorly myelinated projection neurons with disproportionately long axons in relation to their somata (Braak, H. *et al.*, 2003b). It is noteworthy that dopamine-containing cells within the olfactory bulb are increased twofold in PD, at least in its later stages, despite the bulb's early involvement in the degenerative process and evidence of altered function (Huisman, E. *et al.*, 2004). The reason for this paradoxical finding is not known, although it may relate to the repopulation of periglomerular cells from progenitors within the anterior subventricular zone that migrate to the olfactory bulb via the rostral migratory stream (Saino-Saito, S. *et al.*, 2004).

4.46.5.11.5 Progressive supranuclear palsy

PSP, a disorder that accounts for approximately 4% of patients with parkinsonian symptoms, is commonly misdiagnosed as PD since it shares many motor features with PD. Unlike PD, however, tremor is rarely present in this disorder, and the parkinsonian features are less responsive to anti-PD medications (Jackson, J. A. *et al.*, 1983). Compared to PD, PSP is typically characterized by more frontal lobe dysfunction, more neuronal degeneration within the basal ganglia and upper brain

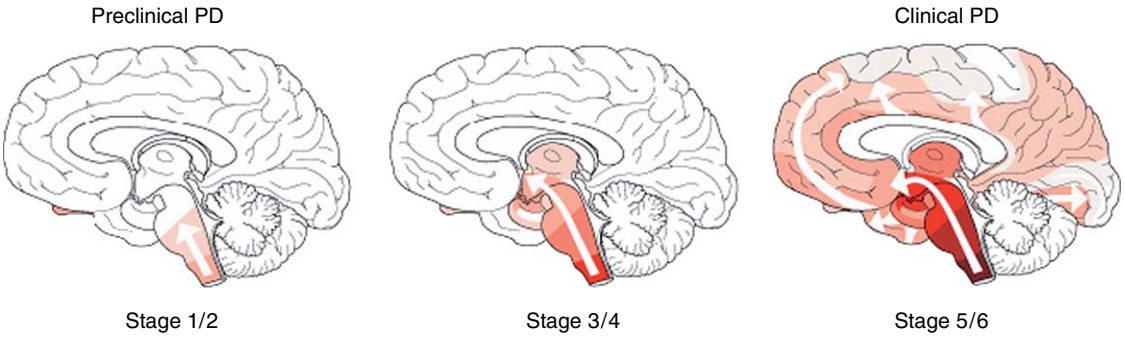

Figure 7 Parkinson's disease (PD)-related Lewy body pathology evolves in predictable stages. According to the staging system of Braak, Lewy bodies (LB) first form within in the olfactory bulb and dorsal motor nucleus of the vagal nerve (stage 1). In stage 2 and stage 3, LB pathology expands from these induction sites into additional brain stem nuclei (e.g., locus coeruleus and substantia nigra) and then into the amygdala. In stage 5 to stage 6, the pathology extends into the cerebral cortex. Clinical symptoms arise during stage 4 to stage 6 when the pathology involves significant regions of the substantia nigra and related brain areas (from Thal, D. R., Del, T. K., and Braak, H. 2004. Neurodegeneration in normal brain aging and disease 15. Sci. Aging Knowledge Environ. e26.).

stem, and less involvement of mesolimbic and mesocortical dopamine systems (Jankovic, J., 1989). Conceivably because of this difference in distribution of pathology, about half of PSP patients have a normal sense of smell, with the remainder having slight-to-moderate dysfunction. In one study of 22 PSP patients, for example, the mean PSP UPSIT score was approximately 32, compared to a mean PD UPSIT score of approximately 19 and a mean control UPSIT score of approximately 36.

4.46.5.12 Epilepsy

It is widely recognized that olfactory and gustatory auras can occur secondary to seizure activity within the temporal lobes and, more rarely, within the orbitofrontal lobes (Acharya, V. *et al.*, 1998). Examples of taste sensations that have been reported in such cases include peculiar, rotten, sweet, like a cigarette, like rotten apples, and like vomitus (for review, see (West, S. E. and Doty, R. L., 1995). However, some of these tastes likely represent smell sensations that are miscategorized as tastes by both the patients and their physicians.

A number of early olfactory threshold studies reported heightened overall bilateral olfactory sensitivity in patients with epilepsy, particularly prior to an ictal event. More recent studies, however, have not reported such hypersensitivity, conceivably reflecting (1) mitigating influences of modern anti-seizure medications or (2) evaluation of more severe and largely intractable cases. For example, one study reported normal bilaterally determined *n*-butanol odor detection thresholds in 18 epileptic patients relative to 17 controls (Eskenazi, B. *et al.*, 1986), a finding that was confirmed for unilaterally determined odor detection thresholds in 21 epileptic patients (Martinez, B. A. *et al.*, 1993). Similarly, another study of 16 patients with left foci and 14 patients with right foci found no detection threshold deficits on either side of the nose to the odorant phenyl ethyl alcohol (West, S. E. and Doty, R. L. 1995). In contrast to threshold studies, suprathreshold deficits have been reported in epileptic patients, including deficits in odor identification, discrimination, and both short- and long-term memory (e.g., Martinez, B. A. *et al.* (1993) . Prolonged odor event-related potential latencies have also been noted in patients with right-side foci after right-side odorant stimulation, and in patients with left-side foci after left-side odorant stimulation (Hummel, T. *et al.*, 1995).

Small, D. M., *et al.* (1997) observed that patients who had a right anterior temporal lobectomy had elevated citric acid recognition thresholds, but normal detection thresholds, relative to both controls and patients who had undergone left temporal lobectomy. Employing PET, these researchers noted that orally presented citric acid increased regional cerebral blood flow (rCBF) bilaterally in the caudolateral orbitofrontal cortex, but relatively more in the right anteromedial temporal lobe and in the right caudomedial orbitofrontal cortex. They speculated that (1) damage to the area corresponding to the rCBF increase in right anterior medial temporal lobe in normal subjects may account for elevation in taste recognition thresholds in lobectomized patients and (2) taste recognition requires

further processing by structures located in the anteromedial temporal lobe.

4.46.5.13 Migraine

The limited evidence suggests that 20–50% of migraineurs experience olfactory auras, osmophobia (intolerance of odors), and/or taste abnormalities during migraine attacks (Diamond, S. *et al.*, 1985). Moreover, both odorants and tastants can trigger migraine attacks in susceptible individuals (Blau, J. N. and Solomon, F., 1985). Unfortunately, few empirical studies of chemosensory function have been made in migraine sufferers, and consensus is lacking as to the direction of the effects. Hirsch, A. R. (1992) reported that of 67 migraineurs, 12 were either hyposmic or anosmic, a percentage much higher than that expected in the general population. No controls were tested. More recently, Snyder, R. D. and Drummond, P. D. (1997) determined odor recognition thresholds to acetone and vanillin in 20 migraine suffers and 21 controls. Rather than decreased sensitivity, these authors found heightened sensitivity (i.e., lower thresholds) in the migraineurs for the odor of vanillin. Although this was not the case for the odor of acetone, those migraineurs who reported that odors generally seemed stronger during migraine attacks exhibited lower acetone thresholds than those exhibited by the others. Hedonic ratings for concentrated acetone did not differ between the migraineurs and the controls.

4.46.6 Treatment of Chemosensory Disorders

Meaningful treatments are available for some, but not all, patients whose olfactory dysfunction is conductive, including dysfunction resulting from blockage of airflow to the olfactory neuroepithelium or from inflammation within the olfactory membrane proper (for review, see Doty, R. L. and Mishra, A., 2001). Thus, surgical procedures that reduce nasal obstruction can improve olfactory function in some patients. Effective therapies for olfactory loss secondary to allergic rhinitis include allergy management, topical cromolyn, topical and systemic corticosteroid therapies, and surgical procedures to reduce inflammation or obstructions. A brief course of systemic steroid therapy can be useful in distinguishing between conductive and sensorineural olfactory loss, since those with conductive loss will often respond to treatment. However, longer term systemic steroid therapy is not advised. Topical nasal steroids are often ineffectual in returning smell function because the steroid fails to reach the affected regions in the upper nasal passages. Increased efficacy presumably occurs when nasal steroid drops or sprays are administered in the head-down Moffett's position. In patients with obstructive inflammatory disease, swelling of the ostiomeatal complex can prevent drainage from the sinuses causing chronic sinusitis. Antibiotic therapy in combination with control of the allergic symptoms underlying the inflammation is effective in many of these cases. Resistant cases typically require surgery to improve drainage and clear infection (Bromley, S. M. and Doty, R. L., 2002).

It is an empirical question as to whether exercising the olfactory system by repeatedly exposing it to odorants improves olfactory function over time. Animal studies suggest that repeated presentations of an odor may alter detection thresholds (Doty, R. L. and Ferguson-Segall, M., 1989), as well as functional connectivity in higher brain regions (Wilson, D. A. *et al.*, 1985). Moreover, there is evidence, in humans, that repeated presentation of odorants increases sensitivity to them (Doty, R. L. *et al.*, 1981). A recently clinical study on this topic, which is unpublished, suggested that some benefit may accrue by exposing hyposmic subjects to a set of odorants in the morning and evening, although the degree of benefit was small and an atypically low spontaneous return of function was present in the control group (Hummel, T. *et al.*, 2005).

Currently, there are no treatment options for smell loss secondary to congenital or other malformations of the olfactory bulbs or stalks. In general, olfactory dysfunction due to sensorineural causes is difficult to manage, and the prognosis for patients suffering from long-standing anosmia due to upper respiratory illness or head trauma is relatively poor. Most patients who recover smell function subsequent to head trauma do so within 12 weeks of injury (Costanzo, R. M. *et al.*, 1995). Although there are no verified treatments for trauma-related olfactory loss, anti-inflammatory agents may minimize post-traumatic sequelae in some cases. Rat research suggests that application of nerve growth factor onto the olfactory epithelium may alleviate axotomy-induced degenerative changes in the olfactory receptor neurons, although it is not known whether this has any functional consequence or if such a procedure in humans would be efficacious (Yasuno, H. *et al.*, 2000). Rat studies also suggest that estrogens may offer some prophylaxis to neurotoxin-related damage to the olfactory receptor region (Dhong, H. J. *et al.*, 1999).

CNS tumors that impinge upon the olfactory bulbs and tracts, as well as sclerotic tissue within the medial temporal lobes, can be resected in some instances with a resultant improvement in olfaction. Although permanent sensory abnormalities can result from damage to a peripheral nerve supplying taste (e.g., lingual nerve and facial nerve), such damage is amenable to surgical repair, particularly in the first months after the injury (Robinson, P. P. *et al.*, 2000). However, the degree of return of function is highly variable and return of normal function is rare. In a series of 53 patients with prior lingual nerve injury who underwent direct reapposition of the nerve with epineurial sutures, Robinson, P. P. *et al.* (2000) found that 41% more patients could detect some taste solutions postoperatively.

A number of oral infections and inflammatory problems that alter taste function can be treated with appropriate antibiotic or anti-inflammatory medication. Even though a number of dysgeusias spontaneously remit with time (Deems, D. S. *et al.*, 1996), this is not true in all cases, and several interventions have been reported to aid in their resolution. First, those dysgeusias due to medications, such as salty or bitter tastes secondary to the use of drugs (e.g., ACE inhibitors and antifugals), commonly resolve following drug discontinuance, although such resolution may require months after cessation. Second, some pharmacological treatments are available for dysgeusias. Thus, low doses of anticonvulsants can eliminate dysgeusias due to central causes, such as partial seizures. Over-the-counter antioxidants or mineral supplements, such as alpha lipoic acid and zinc gluconate ($140\,\mathrm{mg\,day^{-1}}$), may mitigate some dysgeusias (Femiano, F. *et al.*, 2002; Heckmann, S. M. *et al.*, 2005), although zinc therapies are generally ineffectual for most chemosensory disturbances in the absence of frank zinc deficiencies such as occur in liver and kidney disease (Price, S., 1986). Tricyclic antidepressants (e.g., amitriptyline, desipramine, and nortriptyline) and benzodiazepines are reportedly useful as therapy in some cases. Specialized mouthwashes have been reported to provide symptomatic relief in some patients (e.g., chlorhexidine digluconate, dyclonine HCl) (Lang, N. P. *et al.*, 1988). In cases of dysgeusia or taste loss secondary to hypothyroidism, thyroxin replacement therapy is likely beneficial. Mucosal function and comfort can be provided to some patients with xerostomia and excessive dryness using artificial salivas (e.g., Xerolube) (Bromley, S. M. and Doty, R. L., 2003).

There is some rationale to controlling dysgeusias by applying a local anesthetic, such as a lidocaine or cancor sore solution, to selected sectors of the tongue. One basis for this approach comes from studies by Bartoshuk *et al.* (e.g., Yanagisawa, K. *et al.*, 1998). These authors found that anesthetizing one chorda tympani nerve increases the perceived intensity of bitter substances, such as quinine, applied to taste fields innervated by the contralateral glossopharyngeal nerve. In contrast, perceived intensity of NaCl applied to an area innervated by the ipsilateral glossopharyngeal nerve is decreased. When both chorda tympani nerves are anesthetized, the taste of quinine is intensified and the taste of NaCl diminished in areas innervated by the glossopharyngeal on both sides of the tongue. In about 40% of their subjects, a phantom dysgeusia, usually localized to the posterior tongue contralateral to the anesthesia, appeared in the absence of stimulation. This phantom taste was eliminated when the region of origin was anesthetized.

4.46.7 Summary

Possibly owing to the fact that, historically, most disorders of smell and taste have been difficult to diagnose and treat, physicians often downplay these senses in the routine neurological examination. This is unfortunate when one considers that such disorders are common and profoundly affect a patient's quality of life. The chemical senses largely determine the flavor of foods and beverages and provide an early warning for leaking natural gas, spoiled food, fire, and other adverse environmental situations. Importantly, olfactory disturbances can be an early sign of a number of serious diseases or anomalies, including AD, PD, epilepsy, MS, and schizophrenia. Although some patients initially present with a frank complaint of a smell disturbance, others are unaware of their dysfunction, pointing out the need for routine clinical quantitative assessment, which is now easily performed in the office.

In this chapter, we (1) reviewed the anatomy of the human taste and smell systems, (2) described the major symptoms experienced by patients suffering from chemosensory disorders, (3) described the major causes of chemnosensory dysfunction, and (4) presented up-to-date practical techniques for their management and quantitative evaluation. It is clear from the material reviewed that chemosensory disorders are varied in nature and can result from a

wide range of diseases and disturbances, including such common neurological disorders as AD and idiopathic PD. It is also apparent that while some types of chemosensory disturbances can be treated medically or surgically, in many cases treatment options are limited or nonexistent. Accurate assessment of the dysfunction is of value to both the patient and physician, allowing for a determination of the relative degree of dysfunction and whether the alteration is abnormal relative to a patient's age and gender.

Glossary

nociception The processes of encoding and processing of noxious stimuli by the nervous system.

nociceptive stimulus An actually or potentially tissue damaging event that is encoded by primary nociceptive afferents. Although actual or potential tissue damage is the common denominator of those stimuli that may cause pain, there are some types of tissue damage that are not detected by any afferents, and thus do not cause pain. Therefore, not all noxious stimuli are adequate stimuli of nociceptive afferents. The adequate stimuli of nociceptors are termed nociceptive stimuli, which is a subset of noxious stimuli.

nociceptor A primary afferent nerve fiber that is capable of encoding noxious stimuli. All non-nociceptive afferents (e.g., tactile receptors, warm receptors) do respond to noxious stimuli (mechanical or thermal, respectively), because these stimuli are way above their respective thresholds. But only nociceptors are capable of encoding the relevant properties of those stimuli (e.g., sharpness, heat intensity in the painful range).

noxious stimulus An actual or potential tissue damaging event. This was found to be the common denominator of those stimuli that may cause pain. But there are some types of tissue damage that are not detected by any afferents, and thus do not cause pain. See nociceptive stimulus.

The term adequate stimulus (Kandel, E. R. *et al*., 2000) is used in sensory physiology to describe the class of environmental phenomena that requires the least amount of energy in order to elicit a percept mediated by a particular sensory system, for example, a visual percept can be elicited by a punch to the eye, but light from a television screen needs much less energy for this purpose. The implication from such observations in subjective sensory physiology is that the receptive organs of each sensory system are specialized to detect a corresponding class of environmental phenomena (i.e., photoreceptors in the eye are specialized to detect photons).

It was difficult to transfer this concept to the perception of pain and to the nociceptive system. Many different stimuli may cause pain (e.g., pin prick, burn injury, freeze injury, and inflammation), none of which needs particularly low amounts of energy. Sherrington is credited with identifying the common denominator of those stimuli as being tissue damage (in Greek: νοξη Noxe) or environmental phenomena that threaten to cause such damage. Hence, the adequate stimulus to elicit pain is traditionally called a noxious stimulus. It may be defined as follows.

5.01.1 Noxious Stimulus

A noxious stimulus is an actual or potential tissue damaging event. Noxious stimuli may belong to thermal, mechanical, or chemical modalities of energy supply. Therefore, the sensory organs of the nociceptive system, free nerve endings of thinly myelinated Aδ fibers, and unmyelinated C fibers in the skin and most other tissues, have a characteristic property: most of them are polymodal, that is, they respond to more than one modality of stimulus energy. Some nociceptive nerve endings, particularly those of Aδ fibers, are specialized to be most sensitive to one particular stimulus modality (e.g., either heat or pin prick). The differential

sensitivity spectra of nociceptive afferents suggest that pain quality may be encoded by a similar population code in the nociceptive system as taste quality in the gustatory system (Treede, R. D. *et al.*, 1998).

Polymodality is not the result of a primitive nonspecific responsivity to tissue damage. Instead, it is mediated by specialized signal transduction pathways, some of which have been elucidated at the molecular level (Julius, D. and Basbaum, A. I., 2001). One member of the gene family of transient receptor potential channels (TRPV1), for example, is specifically activated by moderate heat stimuli, low tissue pH, and a class of irritant substances called vanilloids. For most inflammatory mediators, specific receptor molecules are present in the membranes of nociceptive nerve endings.

The topic of this volume of the *Handbook of the Senses* is pain. The taxonomy of the International Association for the Study of Pain (IASP) defines pain as, "An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (Merskey, H. *et al.*, 1979). This definition implicitly refers to the adequate stimulus as identified by Sherrington, in its extended form including potential tissue damage rather than calling for outright tissue damage. There are two good reasons for this extension. First, a system that only responds after tissue damage has occurred, cannot subserve a warning function for the organism. The sensory system that mediates pain sensation (the nociceptive system), however, provides even primitive organisms with an array of protective reflexes that can flexibly respond to threatening environmental challenges. Such a system needs to be sensitive enough to signal impending tissue damage before it occurs. Second, although primary nociceptive afferents, the sensory organs of the nociceptive system, encode different intensities of manifest tissue damage as graded action potential discharge rates (Raja, S. N. *et al.*, 1999), the nociceptor activation thresholds were found to be clearly lower than the intensity needed to damage the skin. In humans as well as many animal species, heating the skin to above 40 °C, cooling to below 30 °C, or punctate pressure around 1–5 bars activates nociceptors, but none of these stimuli damages the skin. In fact, for most people these stimuli are not even painful.

The relatively low peripheral nociceptor activation thresholds allow the nociceptive system to subserve its warning function in a highly flexible and plastic way. The peripheral input can be shut down by descending inhibition, if there is an *a priori* reason to ignore the warning signal. The system can also enhance its response to the warning signal by enhancing the efficacy of its central synapses. This process is called central sensitization and may be considered to be one of the phylogenetically oldest mechanisms of learning and memory (Woolf, C. J. and Walters, E. T., 1991). Primary nociceptive afferents may also enhance their responsiveness to their adequate stimuli, a process called peripheral sensitization (Raja, S. N. *et al.*, 1999). Both peripheral and central sensitization contribute to the warning function of the nociceptive system.

As a warning system, the nociceptive system has gaps in its sensitivity: there are some types of tissue damage that are not detected by any afferents, and thus do not cause pain or any protective behavior. This is a well-known phenomenon in internal organs such as the liver or the brain, where a malignant tumor may cause extensive damage without being noticed by the patient. There is an even more common phenomenon of tissue damage that goes unnoticed by the nociceptive system: damage by ultraviolet radiation (Figure 1). The pain of sunburn always comes too late, after the skin has

Figure 1 The concept of the adequate stimulus to activate the nociceptive system and to elicit pain can be illustrated by this scene. Ultraviolet radiation causes tissue damage, but this noxious stimulus is not detected by the nociceptive nerve endings. Only the inflammatory response of the skin leads to adequate activation of nociceptive nerve endings via chemical mediators, which serve as nociceptive stimuli.

already been damaged. This pain does not signal the initial damage but the body's response by an inflammatory reaction. The ensuing peripheral and central sensitization of the nociceptive system lead to pronounced hyperalgesia of the injured skin to heat and mechanical stimuli, which then serves to protect the skin from further damage. These observations have led to the introduction of a new term, nociceptive stimulus (Cervero, F. and Merskey, H., 1996).

5.01.2 Nociceptive Stimulus

A nociceptive stimulus is an actual or potential tissue damaging event that is encoded by primary nociceptive afferents. In summary, the adequate stimulus to activate the receptive organs of the nociceptive system consists of either actual or potential tissue damage (noxious stimulus). However, not all noxious stimuli are detected by the nociceptive system. Therefore, the adequate stimulus for this system in the strict sense is that subset of noxious stimuli that can be encoded by the nociceptive system (nociceptive stimuli). It is not unusual for a sensory system to encode only a part of the range of environmental phenomena that its receptive organs are specialized for: visual stimuli consist of a restricted range of wavelengths of electromagnetic waves, and auditory stimuli consist of a restricted frequency range of pressure waves in the air. Likewise, nociceptive stimuli consist of a restricted range of actually or potentially tissue-damaging events. Linguistically, the term nociceptive stimulus may appear to be a little odd, as it also implies reception rather than just stimulation, but for exactly that reason it fits well into the broader system of terms in sensory physiology.

According to the concept of the adequate stimulus, nociceptive stimuli are encoded by the nociceptive system, just as visual stimuli are encoded by the visual system and auditory stimuli are encoded by the auditory system. However, a full appreciation of our senses goes beyond these aspects of sensory physiology (Bieri, P., 1995; Metzinger, T., 2000): seeing comprises more than vision, hearing comprises more than audition, and pain comprises more than nociception. This is reflected in the definition of pain as given above that does not relate to any objective observable measure, but refers to the subjective experience of the person in pain.

From the beginning of scientific enquiry there have been two opposing views on the biological meaning of pain. One view proposes that pain is a sense similar to vision or hearing, a component of the sensory repertoire of most animals that warns us of impending damage, gives accurate information to the brain about injuries, and helps us to heal. The inclusion of pain in *The Senses: A Comprehensive Reference,* alongside vision, hearing, or olfaction shows that this view is persuasive. But there has always been an alternative interpretation of pain that denies it being a sense like vision or hearing and attaches to both pain and its opposite pleasure fundamental roles in shaping the emotions and behaviors of the individual. Pain is seen as a trigger of emotional states, a behavioral drive, and a highly effective learning tool. Aristotle, who was the originator of this view, made it very clear: there are only five senses – vision, hearing, touch, taste, and smell. Pain and pleasure are not senses but passions of the soul.

Whether or not pain is a sense like the others is not just an academic exercise. The experimental paradigms used to study the nervous system can be fundamentally different depending on the theoretical approach to the object of the study. If pain is regarded as a sense, like vision or hearing, then we will look for sensors that are activated selectively by painful stimuli and for sensory pathways in the brain and spinal cord that carry pain information much in the same way as we identify photoreceptors in the retina and a visual pathway to the cortex. This approach has generated an interpretation of pain mechanisms known as the specificity theory, which maintains that there are elements of the peripheral and central nervous system (CNS) specifically and exclusively dedicated to the processing of pain-related information.

However, if pain is not a sense like vision or hearing, then we do not need to look for a specific neural machinery for its processing but for patterns of activation, spatial or temporal, in neurons that do not necessarily have time-locked responses to painful stimuli. If pain is a passion of the soul then we need distributed networks and interactive parallel processing and not a pain pathway. This view has been articulated throughout the last 100 years as the pattern theory of pain, denying the existence of dedicated sensory elements for pain processing and attributing the perception of pain to interactions between patterns of impulses in nonspecific neuronal networks. The influential gate theory of pain (Melzack, R. and Wall, P. D., 1965) is the best contemporary example of such an interpretation.

The specificity theory of pain was a natural development of the Doctrine of Specific Nerve Energies put forward by the German physiologist Johannes Müller in the nineteenth century. The basic proposal of Müller's doctrine is that each sensory modality is the result of the activation of a specific neural system in the brain. If we are able to perceive touch it is because we have a subset of cells in our peripheral and CNS that respond to touch; if an animal can perceive infrared light or an electromagnetic field then it must have a subset of neurons capable of sensing and processing these stimuli. As he put it: "Sensation is not the conduction of a quality or state of external bodies to consciousness, but the conduction of a quality or state of our nerves to consciousness, excited by an external cause" (Müller, J., 1835–1840). At the end of the nineteenth century, von Frey M. (1895) extended Müller's doctrine to pain sensation, thus reinforcing a strict sensory interpretation of pain. He proposed that the fine nerve endings of unmyelinated afferents were the pain receptors in the periphery and that there was a specific pain pathway taking their signals to the brain. This influential proposal is responsible for the well-known model of pain mechanisms often found in textbooks whereby a pain receptor in the periphery is activated by a noxious stimulus and sends impulses to the spinal cord and from there to the thalamus and cortex via a crossed spinothalamic

pathway. In other words, a relatively simple and straight forward pain pathway (Figure 1(a)).

In contrast, the pattern theory of pain represents a development of the Aristotelian concept of pain as a passion of the soul and was articulated in modern form by Goldscheider A. (1898) at the turn of the nineteenth century. The basic proposal is that pain is the result of intense stimulation of peripheral receptors, regardless of modality and tissue origin. For the pattern theory the neural substrate of pain perception consists of sequences of impulses in peripheral and central neurons that lead to pain sensations when certain spatial and temporal patterns of activity are produced. The emphasis of this interpretation is on patterns of neural activity evoked in the brain by a painful stimulus. In the 1960s, the gate theory of pain proposed a specific neural mechanism located at the first afferent relay in the spinal cord to illustrate how patterns of impulses in sensory receptors could lead to the modulation of pain sensation (Figure 1(b)). The gate theory emphasized the dynamic and plastic components of pain sensations and drew attention to pain modulation as opposed to an interpretation of pain exclusively as an alarm system. It also focused the attention of many researches on the clinical aspects of pain, away from physiological pain, which contributed a surge of studies on the effects of neuropathic lesions and on the development of animal models of inflammatory and pathological pain (see Cervero, F., 2005 for a recent discussion on the gate theory).

The considerable amount of new information about pain mechanisms gathered in the last 40 years has relegated the specificity versus pattern argument to a secondary role. It is now well established that there are specialized sensors in the skin, muscles, and viscera of most animals that are activated exclusively by stimuli that cause injury and whose excitation leads to the sensation of pain (Belmonte, C. and Cervero, F., 1996). It is also known that pain cannot be evoked, under normal circumstances, by changing the patterns of activation of tactile sensory receptors (Ochoa, J. and Torebjork, E., 1983; 1989). There are also substantial data showing that there are neurons in the spinal cord and brain driven mainly or exclusively by nociceptive stimuli (Hunt, S. P. and Mantyh, P. W., 2001). However, there is also significant experimental evidence in favor of plasticity in the nociceptive sensory channel and of the existence of dynamic processes that can alter profoundly the functional properties of peripheral nociceptors and of nociceptive central neurons (Treede, R. D. *et al.*, 1992; Hunt, S. P. and Mantyh, P. W., 2001; Julius, D. and Basbaum, A. I., 2001). It has also been demonstrated that following a peripheral injury or inflammation, the activation of tactile afferents from uninjured skin can evoke pain sensations (see Cervero,

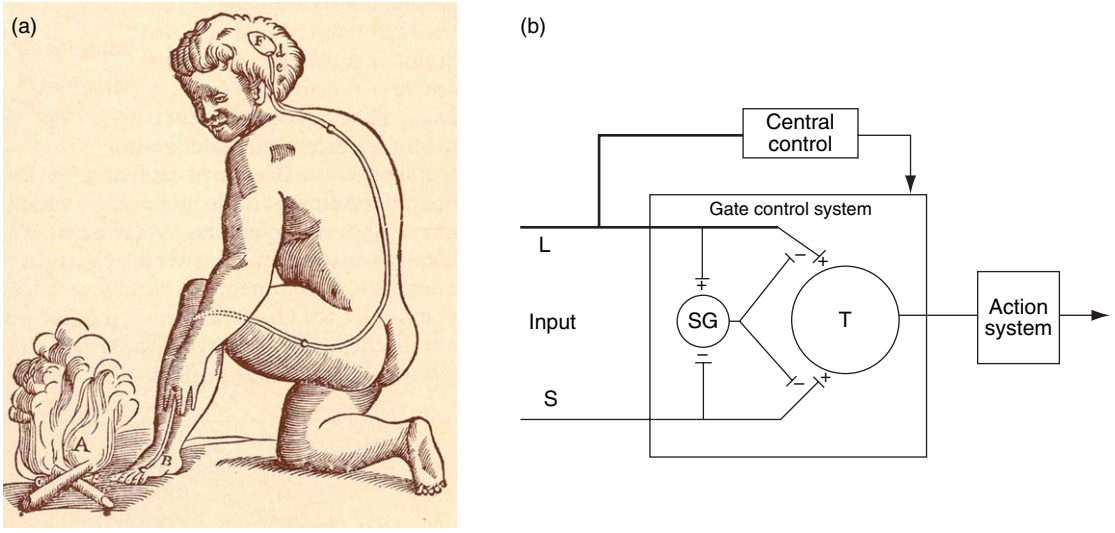

Figure 1 (a) Descartes' drawing of a pathway-oriented pain mechanism. The fire activates pain nerves in the foot of the child and these signals are transmitted to the brain where they are reflected into motor nerves that draw the foot away from the fire. (b) Schematic diagram of the gate theory of pain mechanisms. The diagram shows the presynaptic interaction model between large (L) and small (S) afferent fibers and the key role of substantia gelatinosa (SG) neurons controlling the activity of transmission (T) cells. (a) From Descartes, R. 1664. L'homme. Chez Jacques Le Gras. (b) Reprinted with permission from AAAS from Melzack, R. and Wall, P.D. 1965. Pain mechanisms: a new theory. Science 150, 971–979.

F. and Laird, J. M. A., 1996). Clearly, a point has been reached where neither a strict specificity nor a pattern interpretation can account for all that it is known about pain mechanisms.

We now realize that there are many different forms of pain (acute, traumatic, inflammatory, and neuropathic) and that pain is a dynamic process that cannot be explained with a single theory or a unique mechanism. One of the most striking expressions of the dynamic nature of pain sensation is its lack of adaptation. A continuous and uniform visual or auditory stimulus leads to sensory adaptation; we simply stop feeling this stimulus after a few seconds or minutes. However, the sensation of pain not only does not adapt to a continuous noxious stimulus but gets progressively worse so that, after a few minutes of persistent stimulation with a relatively mild painful stimulus, the sensation becomes unbearable. This change in pain sensitivity generates a state of pain amplification or hyperalgesia that is normally triggered and maintained by a persistent noxious stimulus but that can, under pathological circumstances, appear without an obvious cause so that the normal relationship between injury and pain is lost. Hyperalgesia and allodynia are the main symptoms of many chronic pain states and is the property of pain sensation that makes it particularly unpleasant and often unbearable.

In psychophysical terms a hyperalgesic state is represented by a leftward shift that occurs, following a peripheral injury, in the curve that relates stimulus intensity to pain sensation (Cervero, F. and Laird, J. M. A., 1996) (Figure 2). This shift causes the lower portion of the pain curve to fall in the innocuous stimulus intensity range (allodynia or pain produced by an innocuous stimulus) whereas the top portion shows an increased pain sensation to noxious stimuli (hyperalgesia proper or increased pain sensitivity to a noxious stimulus). Allodynia and hyperalgesia provide protective mechanisms to the organism, preventing the individual from stimulating an injured area and in so doing helping the healing process.

There are two forms of hyperalgesia: primary and secondary. Primary hyperalgesia is an increased pain sensitivity that occurs at the site of injury and it is the consequence of nociceptor sensitization, that is, the increased firing of peripheral nociceptors at the site of injury whose excitability has been increased by a number of locally released sensitizing agents. These sensitized nociceptors send enhanced afferent discharges to the CNS thus evoking increased pain from the primary hyperalgesic area and contributing

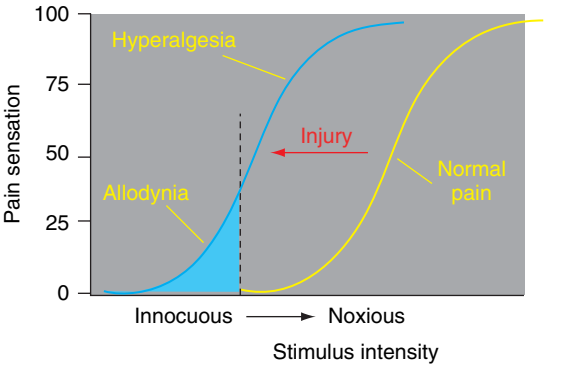

Figure 2 Diagram illustrating the changes in pain sensation induced by injury. The normal relationship between stimulus intensity and the magnitude of pain sensation is represented by the curve at the right-hand side of the figure. Pain sensation is only evoked by stimulus intensities in the noxious range (the vertical dotted line indicates the pain threshold). Injury provokes a leftward shift in the curve relating stimulus intensity to pain sensation. Under these conditions, innocuous stimuli evoke pain (allodynia). Reproduced From Cervero, F. and Laird, J. M. A. 1996. Mechanisms of touch-evoked pain (allodynia): a new model. Pain 68, 13–23, used with permission.

to the alterations in central processing that are, in turn, responsible for secondary hyperalgesia (Treede, R. D. *et al.*, 1992).

Secondary hyperalgesia is defined as an increased sensitivity to pain occurring in areas adjacent or even remote to the site of injury. For instance, following an injury to the hand an area of hyperalgesia may develop covering the entire arm or an inflammation of the gastrointestinal tract or the bladder may produce an area of hyperalgesia in the abdominal or pelvic regions. Secondary hyperalgesia is the result of an alteration in the processing by the CNS of impulses from low-threshold mechanoreceptors, such that, these impulses are able to activate nociceptive neurons and evoke pain. This central alteration is initially triggered and later maintained by the enhanced afferent discharges from the primary hyperalgesic area (Treede, R. D. *et al.*, 1992).

Different forms of pain are mediated by different mechanisms which participate in various ways in the generation of pain and hyperalgesia (Cervero, F. and Laird, J. M. A., 1991; Klein, T. *et al.*, 2005). Generally speaking we can identify three different forms of pain taking into account the relationship between noxious stimulus and pain sensation: nociceptive, inflammatory, and neuropathic (also called phase 1, 2, and 3 pains by Cervero, F. and Laird, J. M. A., 1991) (Figure 3). Nociceptive pain refers to the processing

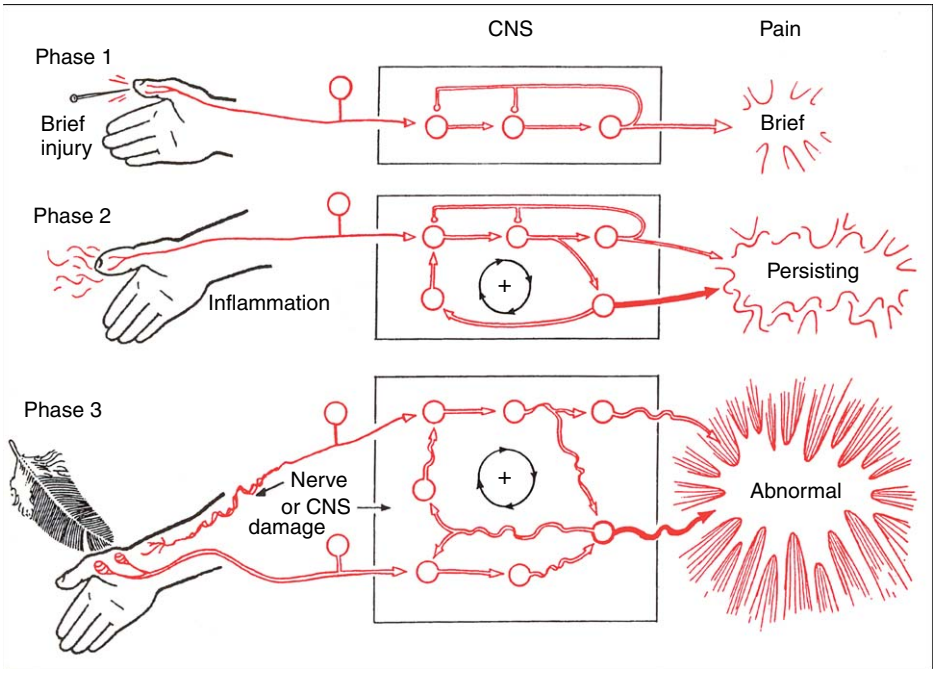

Figure 3 Diagram showing the three models of pain processing for the three main types of pain (nociceptive, inflammatory, and neuropathic or phases 1, 2, and 3). See text for further explanation. Reproduced from Cervero, F. and Laird, J. M. A. 1991 One pain or many pains? A new look at pain mechanisms. News Physiol. Sci. 6, 268–273, used with permission.

of brief noxious stimuli; inflammatory pain is the consequence of prolonged noxious stimulation leading to tissue damage; and neuropathic pain is the consequence of neurological damage, including peripheral neuropathies and central pain states.

Nociceptive pain is a protective sensation needed for the survival and well-being of the individual. The mechanisms subserving the processing of brief noxious stimuli can be viewed as a fairly simple pathway that carries impulses in peripheral nociceptors centrally toward the thalamus and cortex and leads to brief pain perception. In contrast, injury and tissue damage evoke an inflammatory reaction as part of the healing process and generate a pain state different from nociceptive pain as the response properties of the various components of the nociceptive system change. These changes include nociceptor sensitization and recruitment of populations of previously unresponsive receptors. In turn, CNS neurons show an amplification of their excitability expressed as increases in receptive field size and greater spontaneous and evoked firing. All of these changes indicate that the CNS has moved to a new, more excitable state as a result of the noxious input generated by tissue injury and inflammation. Under these conditions, an immediate correlation between discharges in peripheral nociceptors and pain perception is lost.

Neuropathic pain syndromes are the consequence of damage to peripheral nerves or to the CNS itself and produce pain sensations well outside the range of the sensations produced by the normal nociceptive system, even after serious peripheral injury or inflammation. These include spontaneous pain, greatly reduced pain thresholds, and mechanical allodynia. Neuropathic pain states are characterized by an almost complete lack of correlation between peripheral noxious stimuli and pain sensation and are produced by neurological lesions that cause abnormal impulse activity generated in nerve sprouts, neuromas, or in dorsal root ganglion cells, ephaptic coupling between adjacent nerve fibers and abnormal responses of peripheral nociceptors and CNS neurons. Nociceptive and inflammatory pains are symptoms of peripheral injury, whereas neuropathic pain is a symptom of neurological disease.

Whereas the specificity theory can explain fairly well the simpler forms of pain, such as a pin prick or the acute pain of a minor burn, complex pain experiences, including hyperalgesic states require substantial peripheral and central plasticity such that low-intensity stimuli evoke pain (i.e., secondary

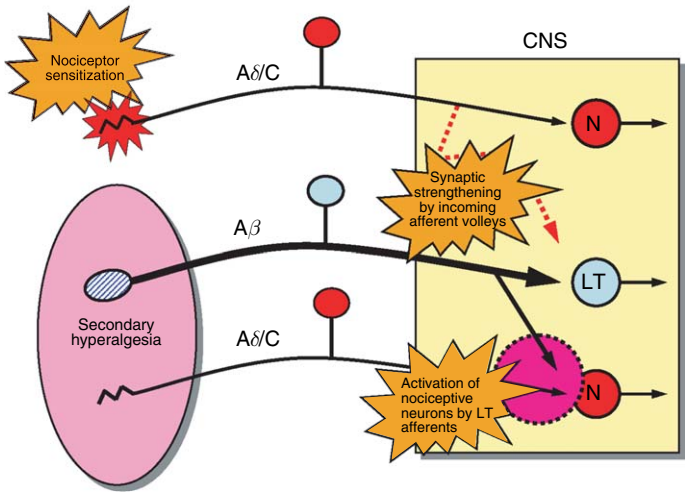

Figure 4 Diagram representing the basic mechanisms of primary and secondary hyperalgesia and the three key processes implicated in their generation. Primary hyperalgesia is produced by the stimulation of nociceptors connected to Aδ- and C-afferent fibers which activate nociceptive CNS pathways (N). Secondary hyperalgesia is produced by stimulation of tactile receptors connected to Aβ-afferents which normally activate low-threshold (LT) pathways but that as a consequence of the amplification of the nociceptive input from the injured area can now access nociceptive neurons (N). See text for further explanation.

hyperalgesia or touch-evoked allodynia). It is very likely that both specific and nonspecific nociceptive systems participate in the generation and maintenance of different pain states.

We can currently identify three key processes in the neurobiological approach to the mechanisms of pain and hyperalgesia: (1) the process of nociceptor activation and sensitization, responsible for the initial signaling of injury and the peripheral changes in the nociceptive system induced by a noxious stimulus; (2) the process of central amplification of nociceptive signals, known as central sensitization, generated by synaptic strengthening of connections between CNS neurons and responsible for the enhanced excitability that accompanies persistent pain states; and (3) the process whereby activity in low-threshold sensory receptors from undamaged peripheral areas can access the nociceptive system and evoke pain sensations and hyperalgesic states (e.g., touch-evoked pain, tactile allodynia) (Figure 4).

The analysis of these three processes supersedes interpretations of pain based on a specificity or pattern approach as all three contain elements that require the existence of groups of neurons dedicated to the processing of nociceptive signals as well as the expression of functional changes induced by afferent activity. Several of these changes can lead to major alterations of pain sensitivity through quite separate mechanisms. For instance, touch-evoked pain can be the result of sensitization of peripheral nociceptors leading to decreases in their activation threshold or be mediated by a purely central mechanism whereby low-threshold mechanoreceptors access nociceptive neurons. The emphasis has moved from theoretical interpretations based on a specific pain channel or on patterns of impulses to the in depth analysis of the functional processes that may cause the different pain and hyperalgesic states. Neither the specificity nor the pattern theories have been able to provide workable models for all forms of pain sensation. They still offer a useful theoretical framework for some of our observations but the weight of work has shifted to studying those processes that will help the development of effective pain relief therapies.

Glossary

anterograde transport Intra-axonal transport in the distal direction (away from the soma) of substances synthesized in (or injected into) spinal or cranial ganglion cells. The transport is brought about by molecules (kinesin for anterograde, and dynein for retrograde, transport) that bind substances and vesicles and move along the microtubules in the axoplasm.

axon reflex Release of neuropeptides from a branch of a nociceptor when the branch is invaded antidromically (against the normal direction of propagation) by action potentials. The released neuropeptides influence the microcirculation in the vicinity of the ending.

deep somatic tissues All subcutaneous tissues that are not viscera, namely tendon, fascia, muscles, ligaments, and joints.

epitendineum (peritendineum externum) Dense connective tissue with blood vessels, lymphatic vessels, and nerve fibers surrounding a tendon.

group I–IV fibers Nomenclature for afferent fibers that originate in deep somatic tissues. Group IV fibers correspond to C-fibers from the skin, and group III to Aδ-fibers. Group I fibers comprise the primary endings from muscle spindles (Ia-fibers) and Ib-fibers from Golgi tendon organs. Group II fibers and cutaneous Aβ-fibers are largely identical. The denominations using roman numerals are based on the diameter of the nerve fibers, those using arabic letters on the conduction velocity.

noceffector This term was coined by Kruger L. (1988) for nociceptors in the tooth; it emphasizes the efferent function of the receptor. Efferent function means that the receptor is involved in the maintenance of the tissue under normal and pathological circumstances by releasing substances stored in the ending. One aspect of such a noceffector role in the skin would be regulation of Langerhans cell type expression and proliferation of keratinocytes. Under pathophysiological circumstances, the effector role of a nociceptor is reflected in the axon reflex (see above) and neurogenic inflammation.

paciniform corpuscle A rapidly adapting mechanoreceptor with a morphology similar to that of a Pacinian corpuscle. It consists of a layered capsule that surrounds a central receptive core. The capsule is derived from the perineurium; the central core contains the receptive portion of the axon with Schwann cells around it. Compared to the Pacinian corpuscle, the paciniform corpuscle is smaller and has fewer laminae in its capsule. In skeletal muscle, it is often supplied by a group III fiber.

primary afferent unit The first sensory neuron in the body periphery. It includes the receptive ending, the afferent fiber, the soma in the spinal or cranial ganglion, and the central process in the dorsal root and the central nervous system (CNS).

receptor matrix An arrangement of cell organelles (mitochondria, vesicles, and axonal reticulum, i.e., a network of fluid-filled vacuoles) embedded in a granulated axonal cytoplasm.

Ruffini corpuscle A flat, encapsulated mechanoreceptor supplied by several myelinated nerve fibers. The fibers form a dense arborization within a capsule of connective tissue.

sensory terminal tree The preterminal axon and its branches. The term is part of the concept that both group III and IV endings do not have just one sensory site, but possess several branches with many receptive loci that together enhance the sensitivity of the free nerve ending as a sense organ.

varicosity An expansion of the preterminal axon of a slowly conducting sensory fiber (Aδ- or C-fiber). The varicosity contains mitochondria, vesicles, and other cell organelles. It is discussed as a receptive site. The varicosities of a free nerve ending are connected by thin stretches of axon; this arrangement causes the beaded appearance of a free nerve ending and the preterminal axon under the light microscope.

5.03.1 Introduction

Originally, pain was assumed to be an emotion like pleasure and fear. In the nineteenth century, this concept was replaced by the view that pain is due to activation of a set of specialized nerve endings. Von Frey M. (1894) was the first to link pain to fine nerve terminals in the skin. The functional term nociceptor is derived from the Latin word *noxius* for damaging or harmful. It denotes a sensory ending that detects actual or potential tissue damage. When activated, it may cause pain in humans and pain-related reflexes in animals. Another definition of a nociceptor is an ending that by its discharge behavior is capable of distinguishing between an innocuous and a noxious stimulus. An important point for the understanding of the function of nociceptors is that their stimulation threshold is just below tissue-damaging intensity. The function of nociceptors is not to signal existing tissue damage, but to inform the central nervous system (CNS) when stimuli approach tissue-threatening intensities.

Nociceptive endings are present in almost all tissues and organs of the organism. However, the fact that lesions of the brain and parenchyma of the lung, liver, and cartilage are not painful suggests that in

these tissues nociceptors are not present. Conversely, by stimulation of cornea, dura mater, and tooth pulp, pain is the predominant or only sensation that can be elicited. These observations led to the assumption that these tissues are equipped exclusively with nociceptors.

The available clinical and experimental evidence indicates that small-diameter afferent fibers have to be activated in order to elicit pain. These fibers conduct action potentials at a relatively slow velocity (below 30 m s^{-1} in the cat); histologically they comprise either thin myelinated (Aδ- or group III) fibers or nonmyelinated (C- or group IV) fibers. However, there are also nociceptors supplied by faster-conducting thick myelinated Aα/β-fibers: in the rat, approximately 20% of all Aα/β-fibers are nociceptive (for review, see Djouhri, L. and Lawson, S. N., 2004). The nomenclature with roman numerals (group I–IV fibers) was developed by Lloyd D. P. C. (1943) for muscle afferent fibers. It is now being used for afferent fibers from muscle, joint, tendons, and fascia (the so-called deep somatic tissues).

Generally, there is a negative relationship between mechanical threshold and conduction velocity (CV) of sensory afferents: the higher the CV, the lower the mechanical threshold (Burgess, R. P. and Perl, E. R., 1967). In the dorsal root ganglion (DRG), the correlation between soma diameter and axonal CV is weaker than generally thought. In Figure 1 (Hoheisel, U. and Mense, S., 1987), this correlation is shown for intracellularly stained DRG cells of the cat. For group III units (those having CVs between 2.5 and 30 ms^{-1}), there was no significant correlation between soma size and CV, and for group IV units (conducting at <2.5 ms^{-1}), the correlation was negative. Thus, from the soma size in the DRG, the diameter or CV of group III and IV afferent fibers cannot be inferred. Generally, the majority of nociceptive free nerve endings will originate from small-diameter DRG cells, but there are also relatively large somata that supply nociceptive terminals. Conversely, not all the small DRG cells supply nociceptive endings.

In morphological studies on the endings of unmyelinated fibers, the first hurdle to be taken is the distinction between efferent and afferent units, because postganglionic sympathetic fibers may look identical to unmyelinated afferent ones, except that the former have a larger mean diameter (Heppelmann, B. *et al.*, 1988). The presence of

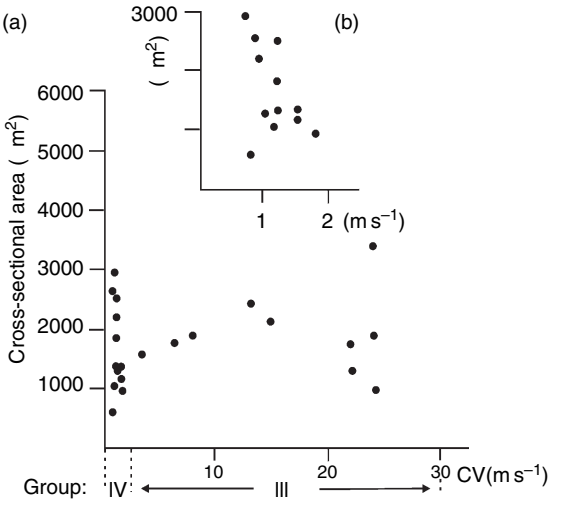

Figure 1 Relationship between cross-sectional area of dorsal root ganglion (DRG) cells and conduction velocity (CV) of the peripheral axon. (a) Data from 12 unmyelinated (C- or group IV) fibers and 10 thin myelinated (Aδ- or group III) fibers. (b) Data from the unmyelinated units at an expanded scale of the abscissa. There was no significant correlation between soma size and CV within group III fibers, and for group IV units the correlation was negative. (Modified from Hoheisel, U. and Mense, S., 1987, with permission).

neuropeptides may be helpful, since for instance CGRP is absent from postganglionic sympathetic fibers (Ju, G. *et al.*, 1987). However, postganglionic parasympathetic fibers have also been shown to contain neuropeptides. Therefore, if neuropeptide-immunoreactive (ir) free nerve endings are being studied, one has to assume that a certain (probably small) proportion of the endings originate from autonomic efferent fibers. Of course, the best way of eliminating this problem is to cut the autonomic supply to the studied body region.

Not all small-diameter, slowly conducting afferent fibers are nociceptive. In cutaneous nerves, there are thermoreceptors and low-threshold mechanoreceptors that have unmyelinated afferent fibers, and also in skeletal muscle low-threshold mechanoreceptors with group IV afferents can be found (Light, A. R. and Perl, E. R., 2003; Hoheisel, U. *et al.*, 2005). The presence of certain neuropeptides such as CGRP does not distinguish between high- and low-threshold mechanosensitive (HTM and LTM) group IV units, because the neuropeptide was found in both functional types (Hoheisel, U. *et al.*, 1994).

The development of myelinated nociceptors has been reported to depend upon the presence of trkA (tyrosin kinase A) and trkC receptors in the DRG, but not upon trkB receptors (Ichikawa, H. *et al.*, 2004). The trk receptors bind neurotrophins (NTs) selectively; the ligand for trkA is nerve growth factor (NGF), that for trkB, brain-derived neurotrophic factor (BDNF), and that for trkC, NT-3.

Even though several groups have studied and described the structure of putative nociceptors, clear morphological (light or electron microscopic) differences between the various functional types of nociceptor are not apparent. The functional differences are probably due to the equipment of the endings with different sets of receptor molecules (Cesare, P. and McNaughton, P., 1997).

In neurophysiological experiments on cats and rats, an unexpected finding was that many unmyelinated afferent units had two receptive fields (RFs), i.e., the same fiber could be activated by applying stimuli to more than one location. In the deep tissues of the cat tail, afferent units were found that had one RF in deep tissues (muscle, joint, and periosteum) and another one in the skin distal to the deep RF (Mense, S. *et al.*, 1981). Sometimes, the distance between the RFs could be several centimeters. The anatomical basis of this feature may be branching of the afferent fiber close to its area of termination. Anatomical and neurophysiological studies (Devor, M. *et al.*, 1984; Pierau, E.-K. *et al.*, 1984) have shown that afferent units with long branched axons are rare (a few percent of all afferent fibers), but they may be functionally relevant, since they are likely to reduce the spatial resolution of the nociceptive system, and thus could contribute to the diffuse nature of deep pain.

The data that are most important to this chapter were obtained in studies employing a combination of electrophysiological and neuroanatomical techniques, because otherwise one does not know if a given free nerve ending in a histological section has a nociceptive function. However, many purely morphological investigations on free nerve endings yielded results that are relevant to this chapter, even though the evidence for a nociceptive function is indirect. Therefore, many of these studies are included below.

The main emphasis of this chapter is on nociceptors or free nerve endings, respectively, in skin, muscle/joint, tooth pulp, and testis, because large sets of data are available from these tissues.

5.03.2 General Morphological Features of Nociceptors

5.03.2.1 Light Microscopic Structure

Morphologically, a nociceptor is a free nerve ending that is usually connected to the CNS through thin myelinated or unmyelinated nerve fibers. (As stated above, there are also nociceptors with thick myelinated fibers.) C- or group IV fibers are assumed to terminate exclusively in free nerve endings while group III fibers supply both free nerve endings and other types of receptors (for instance in muscle paciniform corpuscles; Barker, D., 1967; Stacey, M. J., 1969). A frequent location of free nerve endings is the wall of arterioles and the surrounding connective tissue; the capillaries proper do not have a rich supply with these endings (Stacey, M. J., 1969; Reinert, A. *et al.*, 1998). The marked sensitivity of free nerve endings to chemical stimuli, particularly to those associated with disturbances of the microcirculation, may be related to their location in or close to the wall of blood vessels.

The term free nerve ending or unencapsulated ending is derived from the fact that in the light microscope this type of ending lacks a visible (corpuscular) receptive structure (Stacey, M. J., 1969). Typically, such an ending consists of several branches or terminals that altogether form the receptor in the morphological sense. An afferent fiber together with its receptive ending is an afferent unit. In the fluorescence microscope, the receptive ending and the preterminal axon look like a string of beads with relatively wide diameter (so-called varicosities) connected by very thin stretches of axon. The diameter of a branch of a free nerve ending is 0.5–1.0 μm, i.e., at the limits of the resolution of the light microscope. Figure 2 shows a free nerve ending in a rat

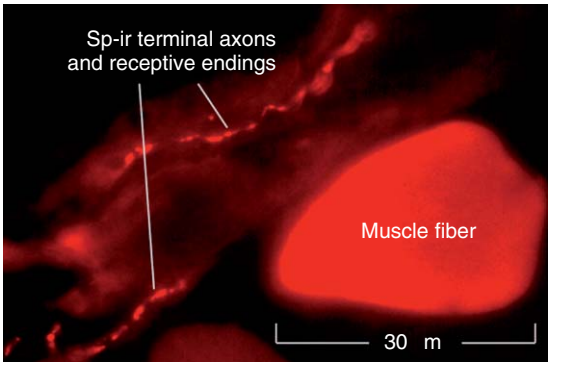

Figure 2 Histological section from rat gastrocnemius muscle showing two nerve fibers with varicosities visualized with fluorescent antibodies to substance P (SP; U. Hoheisel and S. Mense, unpublished data).

skeletal muscle after labeling with fluorescent antibodies to SP.

Most of the unmyelinated afferents enter the spinal cord via the dorsal root. However, there are also unmyelinated afferent fibers in the ventral root: approximately 30% of all ventral root fibers are unmyelinated and 50% of these fibers survive in the distal stump after cutting the ventral root. Therefore, they were assumed to be afferent with their soma located in the DRG (Applebaum, M. L. *et al.*, 1976).

In immunohistochemical studies, sensory free nerve endings have been described as either peptidergic or lectin-positive, the latter being largely peptide free. The lectin-positive endings possess membrane-associated glycoconjugates that bind the plant lectin *Griffonia simplicifolia* isolectin B4 (IB4). They are assumed to be identical to the fluoride-resistant acid phosphatase (FRAP) endings. Many of the IB4-positive endings express the purinergic P2X3receptor. In contrast, the peptidergic endings are equipped with the vanilloid receptor TRPV1 (transient receptor potential subtype V1). These cytochemical differences led to the hypothesis that the IB4-positive and -negative endings represent two functionally distinct classes of nociceptors. (Snider, W. E. and McMahon, S. B., 1998; Stucky, C. L. and Lewin, G. R., 1999). Recent evidence indicates that the peptidergic endings express trkA receptors, are dependent on NGF in their development, and express predominantly tetrodotoxin (TTX)- sensitive Na^+ channels, whereas the nonpeptidergic IB4-positive endings depend on glial cell–derived neurotrophic factor (GDNF) in their development and express more TTX-resistant Na^+ channels than the IB4-negative fibers (Wu, Z.-Z. and Pan, H.-L., 2004). Another difference between these two types of putative nociceptors is that the IB4-positive endings terminate freely in the tissue without close spatial relationship to blood vessels, whereas the peptidergic fibers are often associated with blood vessels (Silverman, J. D. and Kruger, L., 1988; Figure 3). At present, however, the assumption prevails that the separation between these two postulated types is probably not that sharp and that IB4-positive endings may also express TRPV1 receptors.

In experiments employing a combination of electrophysiological and immunohistochemical techniques to study functionally identified DRG cells, Lawson S. N. *et al.* (1997) reported that cells terminating in cutaneous nociceptive endings showed a strong tendency to express SP, particularly if they had a slow CV or small somata in the DRG.

5.03.2.2 Ultrastructure

In electron microscopic studies, often uncertainties remain as to the identity of the ending. Even when in combined electrophysiological–morphological investigations an ending is first functionally characterized and then morphologically reconstructed, it is sometimes difficult to make sure that a given ending in a histological section is the one that was studied functionally.

The published findings demonstrated that free nerve endings are not free in the strict sense, because the majority are ensheathed by Schwann cells (therefore, the term free nerve ending is a misnomer). Exceptions to this rule are endings in the epidermis

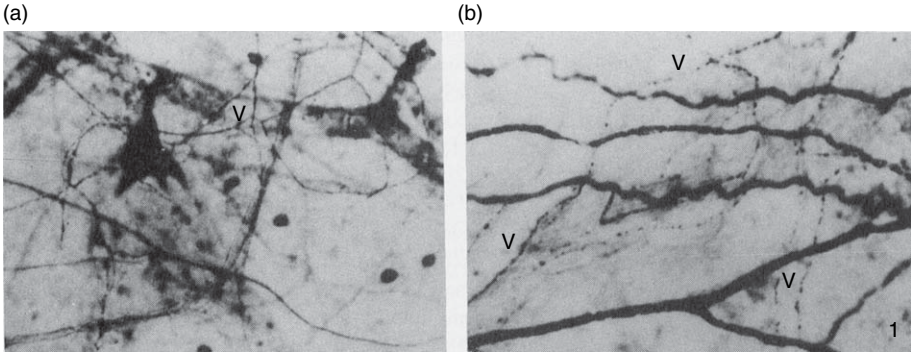

Figure 3 Testicular whole-mount preparation of the rat epididymal tunica vasculosa stained with Griffonia simplicifolia A-B4 lectin (a) and antibodies to calcitonin gene-related peptide (CGRP; (b)). Slender lectin-stained axonal bundles and terminals distribute freely throughout the tissue (a). The lectin-labeled axons bear little relation to blood vessels (V) whose endothelial basal lamina is also lectin-stained. In contrast, CGRP immunoreactivity is evident as heavily labeled coarse nerve bundles from which one can trace fine granular axons running closely adherent to blood vessels (V). (From Silverman, J. D. and Kruger, L., 1988, with permission.)

that lose their Schwann cell covering, when they pass the basal lamina of the epidermal layer (see below). Usually, also the receptive terminals are ensheathed by Schwann cells, and only small areas of the axonal membrane remain uncovered by Schwann cell processes. These areas are separated from the interstitial fluid only by the basal lamina that spans the exposed axonal membrane areas (Andres, K. H. *et al.*, 1985; Heppelmann, B. *et al.*, 1990a; 1990b; Messlinger, K., 1997). The varicosities in the exposed membrane areas are supplied with mitochondria and vesicles and show other structural specializations characteristic of receptive structures, and together with the end bulb they are assumed to be the site where external stimuli act. A reconstruction of such an ending is shown in Figure 4.

The arrangement of cell organelles (mitochondria, vesicles, and axonal reticulum, i.e., a network of fluid-filled vacuoles) embedded in a granulated axonal cytoplasm was called receptor matrix by Andres K. H. and von Düring M. (1973). Often, nociceptive endings exhibit granular or dense-core vesicles containing neuropeptides. However, vesicles containing catecholamines can have the same appearance, so that dense-core vesicles are not an unambiguous sign of a nociceptive ending. The function of the round clear vesicles in the peripheral ending is still obscure. They may contain the same transmitters as the central synaptic terminal (e.g., glutamate). Recent reports have shown that glutamate is an effective stimulant for nociceptive endings in the body periphery (Svensson, P. *et al.*, 2003). Therefore, it is conceivable that nociceptors enhance their own excitation by releasing glutamate when they are activated.

In a recent survey, Kruger L. *et al.* (2003a) list some features that were considered characteristic for nociceptive terminals in the body periphery:

(1) An axonal reticulum that may be derived from the smooth endoplasmic reticulum.
(2) Vesicle aggregates embedded in a granular axonal matrix that may be identical to the receptor matrix described by Andres K. H. and von Düring M. (1973).
(3) Exposed membrane areas that are not ensheathed by Schwann cells and directly contact the basal lamina.

The receptive terminal as a whole consists of several branches equipped with many receptive sites that have the appearance of varicosities. Together the branches constitute a sensory tree as shown in Figure 5 (Messlinger, K., 1996).

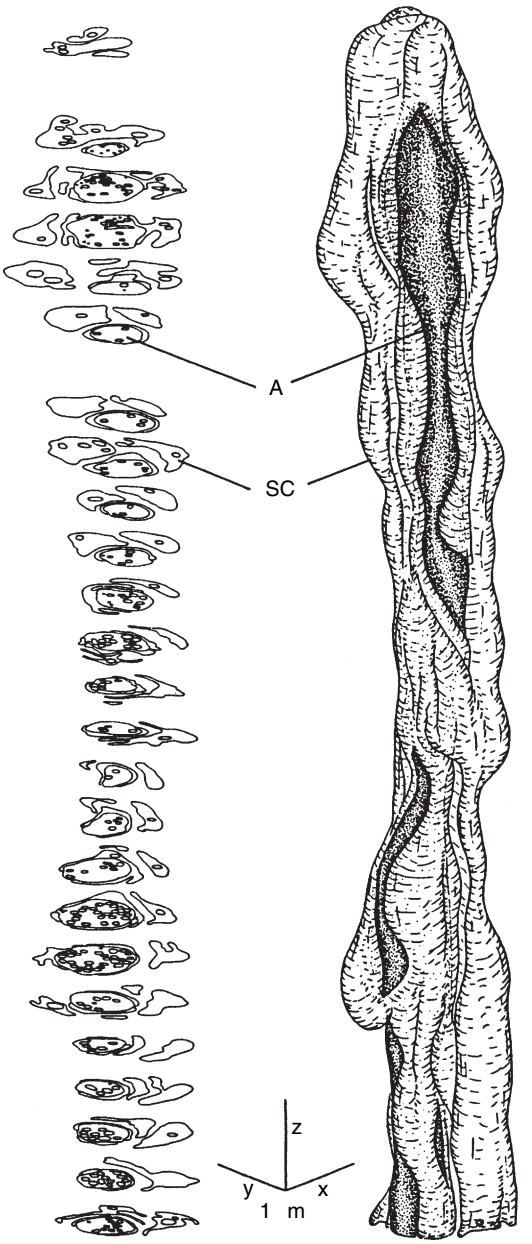

Figure 4 Reconstruction of an end branch of an articular group III ending. *Left*: Contours of the cross-sectioned nerve fiber at a distance of 1 μm each (computer-aided reconstruction). *Right*: Hand drawing based on the stack of sections showing the surface of the end branch. The bare axon areas (A) are densely dotted; SC, Schwann cell. (From Messlinger, K. *et al.*, 1995, with permission.)

It is important to note that the above features cannot be found at the synaptic terminal of the same neuron, i.e., the central and distal terminals of

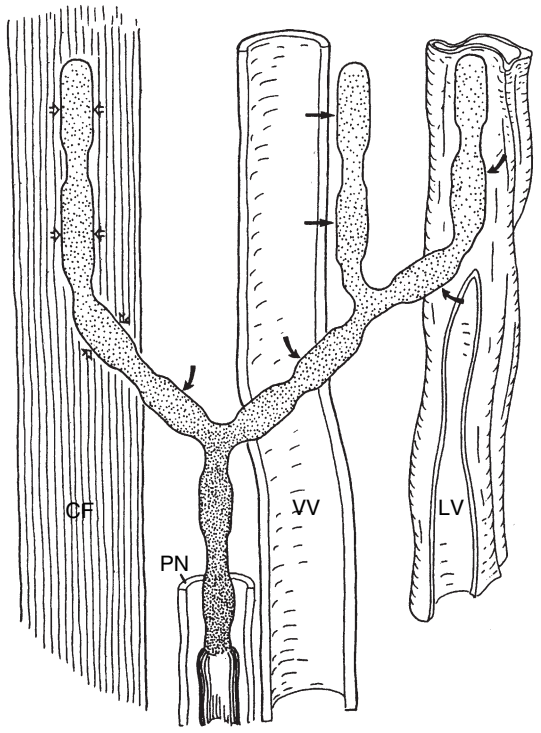

Figure 5 So-called sensory terminal tree of a group III fiber (schematic representation) as a possible morphological basis for sensitization of polymodal nociceptors. The summation of local receptive potentials created in perivascular (chemoreceptive) branches at venous vessels (VV) or lymphatic vessels (LV) in combination with the local potentials of mechanoreceptive branches in collagenous tissue (CF) may lead to a suprathreshold excitation at the basis of the sensory terminal tree within the perineurium (PN). (From Messlinger, K., 1996, with permission.)

a sensory neuron exhibit morphological differences. Small clear vesicles are present at both terminals, but at the peripheral terminal they show diversities in size, shape, and electron lucency, which are not present at the central terminal. The differences in vesicle content between the peripheral and the central terminal are difficult to explain, because if the vesicles are synthesized in the soma, as is generally assumed, a complicated sorting process is required. This is not impossible, because at least for channel proteins an exclusive transport to the peripheral terminal has been reported (Garcia-Anoveros, J. *et al.*, 2001). Another explanation would be that the small clear vesicles in the distal terminal are synthesized in the ending itself, but at present this appears unlikely. As the origin and the contents of the small clear vesicles in the peripheral terminal are unknown, the function of these vesicles is likewise obscure.

One of the characteristic functional properties of a nociceptor is its relatively high mechanical stimulation threshold. The high mechanical threshold is surprising, considering the fact that a free nerve ending is a fragile structure with a semifluid membrane. One factor that may be responsible for the high mechanical threshold is a special mechanosensitive ion channel, the transient receptor potential subunit V4 (TRPV4; Liedtke, W., 2005).

5.03.3 Nociceptors in Various Tissues

A complete overview of all tissues is not attempted. Only those organs/tissues for which comprehensive sets of data are available are addressed below.

5.03.3.1 Skin

The cutaneous nociceptors are generally subdivided into several types according to the fibers supplying them, namely Aδ/β- or C-fibers. Among the receptors supplied by myelinated fibers are (data from monkey, after Djouhri, L. and Lawson, S. N., 2004):

- Type I A mechano-heat receptors (AMH, supplied by Aδ- and Aβ-fibers). They have a relatively low mechanical, but a high thermal, threshold. They are called moderate pressure receptors by some.
- Type II A mechano-heat nociceptors (AMHs, supplied by Aδ-fibers). They have high mechanical and low thermal thresholds.

Among the receptors supplied by C-fibers, which are by far more frequent, are

- C-fiber mechano-heat nociceptors (CMHs), which have little sensitivity to algesic agents
- Cold nociceptors
- Polymodal nociceptors that respond to all noxious stimuli including algesic chemical stimuli

In a cutaneous nerve of the cat, approximately 50% of all unmyelinated afferent fibers were found to have a high mechanical threshold in the noxious range (Bessou, P. and Perl, E. R., 1969). These units also responded to noxious heat and irritant chemicals and therefore were considered to be polymodal nociceptors.

The measured size of the RF of a single unmyelinated fiber supplying a polymodal nociceptor depends on the thickness of the probe used for mechanical stimulation: Thick probes yielded areas of 6–32 mm^2 (mean 18 mm^2) in the rabbit, whereas

with small probes mean areas of 7.5 mm^2 were measured, which consisted of several mechanosensitive spots that could be activated independently from each other (Kenins, P., 1988).

5.03.3.1.1 Light microscopy

The nociceptive endings of the skin can extend in the epidermis to just beneath the surface. This explains why superficial abrasions of the skin can cause pain but no bleeding, because there are no blood vessels in the epidermis.

A study of the distribution of CGRP-ir fibers in the rat glabrous skin (Kruger, L. *et al.*, 1989) revealed a dense network in the subpapillary layer largely confined to dermal blood vessels and sweat glands. The intraepidermal fibers branched extensively in the stratum spinosum, but some extended nearly to the stratum corneum (Figures 6 and 7). These fibers were considered to fulfill a noceffector role rather than a nociceptive one. Noceffector means that these fibers have an efferent function and are involved in the maintenance of the tissue under normal and pathological circumstances (Kruger, L., 1988). One aspect of such a noceffector role in the skin would be regulation of Langerhans cell type expression and proliferation of keratinocytes (Kruger, L. and Halata, Z., 1996). In hairy skin of the rat, a similar arrangement of CGRP-ir fibers was found with the additional feature that the lower portion of each hair follicle exhibited an extensive innervation. Sebaceous glands and arrector pili muscles were not supplied with CGRP-ir fibers.

To find out if the effect of capsaicin treatment of skin pain (e.g., erythralgia) is due to a desensitization or destruction of nociceptive nerve fibers, Simone and coworkers (Simone, D. A. *et al.*, 1998) performed a light microscopic study of capsaicin effects in skin biopsies of human skin. In the epidermal layer of intact skin, mainly fibers ir for PGP 9.5 (protein gene product 9.5, a general marker for nerve fibers) were found, whereas in the dermis a dense innervation of CGRP- and SP-ir fibers was present. After topical capsaicin treatment, the CGRP- and PGP-ir fibers were almost completely gone, but the SP-ir fibers were less affected. Simultaneously, heat pain and pain produced by sharp objects were markedly reduced. This finding is surprising, because most SP-ir fibers are assumed to be nociceptive (Lawson, S. N. *et al.*, 1997).

Recently, unmyelinated fibers stained for PGP 9.5 in the skin of human biopsy material have been studied using confocal microscopy (Kennedy, W. R., 2004). Of interest in the context of the present chapter are fibers that penetrated the basal lamina and branched in the epidermis, because they can be assumed to be free nerve endings. The PGP 9.5-positive fibers in the epidermis had an appearance similar to that described in other reports: From a subepidermal plexus single fibers coursed in the epidermis, where they could be easily counted (Figure 8(a)). In skin biopsies of patients with diabetic neuropathy, the density of the epidermal

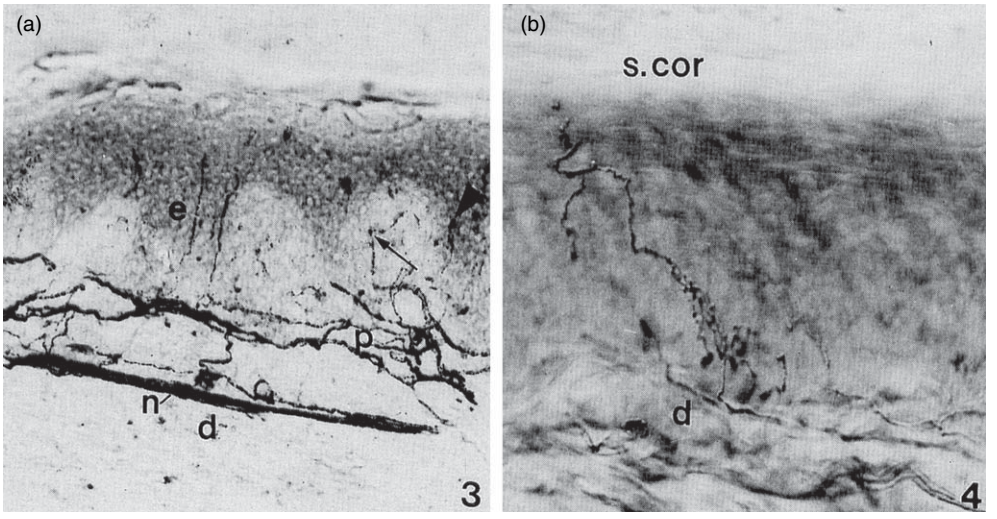

Figure 6 Digital glabrous skin. (a) A dermal (d) cutaneous nerve gives rise to an extensive calcitonin gene-related peptide-immunoreactive (CGRP-ir) subpapillary nerve plexus (p) from which individual axons can be traced into epidermal pegs (e) and dermal papillae (arrow). Some branches appear to end at varying depths within the stratum spinosum revealing terminal expansions (arrowhead) (×63). (b) Branched CGRP-ir axons in palmar glabrous skin extending from the dermis (d) nearly to the stratum corneum (s.cor) (×320). (From Kruger, L. *et al.*, 1989, with permission.)

Figure 7 A dermal calcitonin gene-related peptide-immunoreactive (CGRP-ir) axon terminating as a free nerve ending with a bulbous enlargement (arrow) (×320). (From Kruger, L. *et al.*, 1989, with permission.)

branches was much less, and some fibers showed swellings that were interpreted as an indication of de- or regeneration (Figure 8(b)).

5.03.3.1.2 Electron microscopy

In a combined electrophysiological–electron microscopic study on mechanical nociceptors in the cat skin (Kruger, L. *et al.*, 1981), single receptive endings were first identified functionally in electrophysiological recordings and then examined morphologically. Mechano-nociceptors had RFs consisting of several sensitive spots with relatively insensitive areas in between. After functional identification, the location of the mechanosensitive spots was marked with fine steel pins and the tissue processed for light and electron microscopy. The study focused on afferent units conducting at 20–30 $m\,s^{-1}$, i.e., on myelinated mechano-nociceptors. Some of the thin myelinated fibers approached the papillary layer of the corium (dermis), lost their myelin sheath in this area but retained their Schwann cell layer, and penetrated the epidermal basal layer. The penetration site was considered to be the receptive portion of the ending; here the axons exhibited mitochondria, clear round and dense-core vesicles. Most of the axons that penetrated into the epidermal layer still had a Schwann cell covering (Figure 9), but in some cases the Schwann cell sheath was lost and the basal lamina of the axon fused with that of keratinocytes (Cauna, N., 1966).

Nociceptive endings originating from Aδ-fibers have been reported to terminate in the basal layer of the epidermis, i.e., they do not penetrate into the

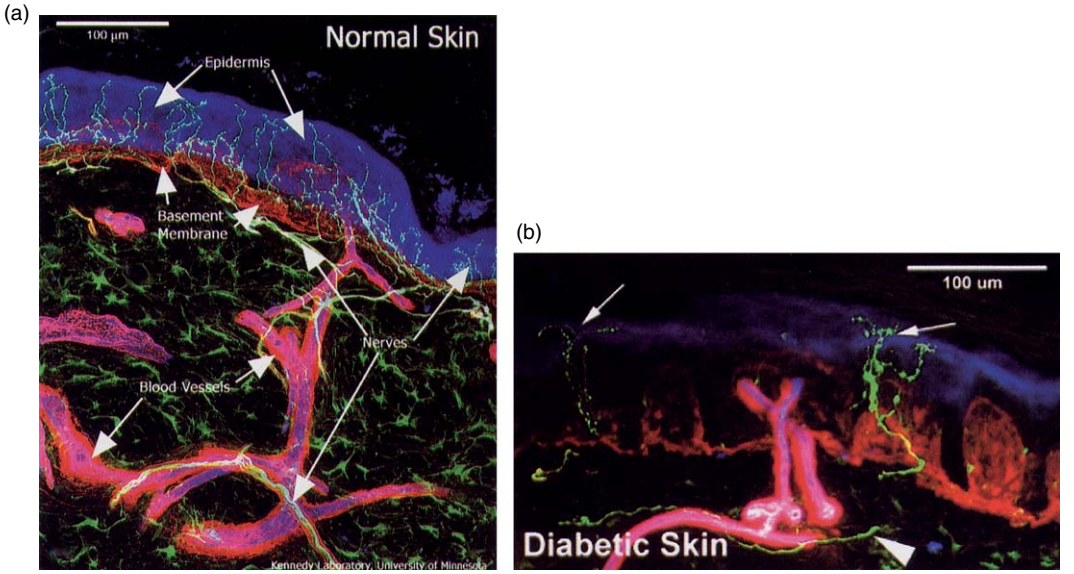

Figure 8 (a) Normal human epidermal and papillary dermis innervation. Nerve fibers (green and yellow) course in bundles through the dermis and branch into the papillary dermis to form the subepidermal neural plexus. Fibers from this plexus penetrate the epidermal–dermal basement membrane (red) to enter the epidermis (blue). Note that the basement membrane surrounding capillaries also appears red and some nonneuronal fibroblasts appear green. Epidermal nerve fibers are abundant and uniformly distributed. (b) Diabetic skin. Two tufts (arrows) arise from the subepidermal neural plexus (arrowhead). Nerve fibers comprising the right tuft have many swellings. Irregular distribution characterized by tufting and clustering of nerve fibers and the presence of swelling is distinctive of neuropathy. (From Kennedy, W. R., 2004, with permission.)

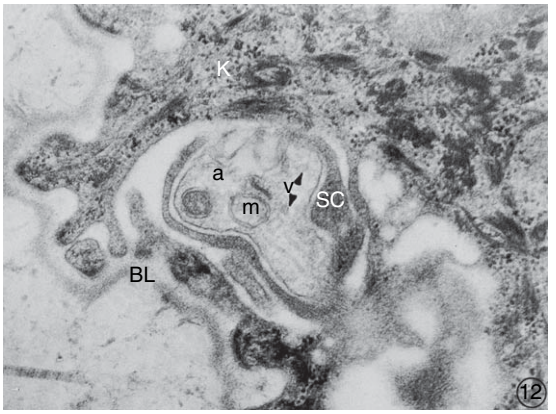

Figure 9 Cat hairy skin. An intradermal axon (a) containing mitochondria (m) and clear vesicles (v) (arrowheads) enclosed by a Schwann cell (SC). The basal lamina (BL) of the keratinocyte (K) is not shared by the Schwann cell, which lacks a basal lamina only within the epidermis (×40 000). (From Kruger, L. *et al.*, 1981, with permission.)

upper epidermal layer (Kruger, L. and Halata, Z., 1996). At present, these endings cannot be morphologically distinguished from cutaneous cold receptors that have the same location (Hensel, H. *et al.*, 1974).

Du J. *et al.* (2003) reported that nociceptive unmyelinated endings in the rat digital nerves exhibit *N*-methyl-D-aspartate (NMDA) receptor molecules type 1 (NMDAR1) and can be excited by glutamate. These data support those of Svensson P. *et al.* (2003). The NMDAR1 were assumed to contribute to the sensitization of nociceptors in inflamed tissue, because they showed an increased expression 7 days after induction of an experimental inflammation.

5.03.3.2 Cornea

Hundred years ago, von Frey assumed that from the cornea only pain can be evoked, but later several reports were published indicating that also sensation of touch, warmth, and cold can be elicited. The corneal epithelium is one of the tissues with the highest innervation density of the body and in this regard is comparable with the tooth pulp.

In an electrophysiological study on fine nerve fibers of the cornea *in vitro*, Aδ-fibers were described that were sensitive to mechanical and heat stimuli. These units were situated in the basal epithelial layer, whereas polymodal C-fiber endings were found in the superficial layers (MacIver, M. G. and Tanelian, D. L., 1993).

Recordings from single corneal sensory fibers demonstrated that the RFs of LTM endings were relatively large with a size of 50–200 mm^2 in the cat (Tower, S., 1940). Most of the slowly conducting (Aδ- or C-) fibers of the cornea were found to be polymodal and responded to mechanical, thermal, and chemical stimuli. They had a smaller RF size of ∼25 mm^2. Acidic solutions were used to test these units, and the endings responded readily to a pH of 5 to 4.5 with a discharge that was nearly proportional to the proton concentration. Capsaicin – a specific ligand for the TRPV1 receptor – was also excitatory for slowly conducting corneal afferents (Belmonte, C. *et al.*, 1991).

In contrast to most other body regions, the cornea is not supplied by blood vessels. Therefore, after a lesion has occurred, blood cells have no rapid access to the damaged area. In this case, lesion-induced sensitization of corneal nociceptors can occur through activation of tissue cyclooxygenase and lipoxygenase-generating prostaglandins (PGs) and other sensitizing agents.

An interesting feature of corneal sensory endings is that the continuous shedding of epithelial cells on the surface of the cornea changes the morphology of the nerve terminals. This results in a rearrangement of the arborization pattern of superficial terminals within 1 week. Also after a relatively mild injury, a remodeling of the corneal sensory ending takes place, and this remodeling is associated with an increased expression of the growth-associated protein (GAP)-43 in the corneal afferents (Belmonte, C. and Gallar, J., 1996). This protein is known to be involved in the development and regeneration of neurons; it is also present in growth cones of regenerating nerve fibers.

5.03.3.2.1 Light microscopy

Light microscopic investigations showed that corneal afferents were either thin myelinated or unmyelinated. As in the skin, they formed a dense plexus in the stroma from which branches ascended through the basal epithelial layer and terminated in bulb-like structures just underneath the corneal surface. In the electrophysiological study mentioned above (MacIver, M. G. and Tanelian, D. L., 1993) the fibers differed in their morphology: Aδ-fibers looked like leashes and polymodal C-fiber terminals like stranded endings under epifluorescence.

As in free nerve endings of other tissues, neuropeptides such as SP and CGRP are present in corneal terminals. Interestingly, in the cornea SP has a trophic effect on the corneal epithelium. The healing of a corneal wound is promoted by external

administration of SP. Conversely, the healing process is delayed if SP is missing in the corneal terminals, e.g., after injection of capsaicin into the retrobulbar space to deplete SP-containing fibers. Generally, SP appears to promote mitosis in epithelial cells of the cornea, while CGRP inhibits it. After corneal irritation or damage, signs of neurogenic inflammation occur such as edema, conjunctivial vasodilatation, and photophobia. These symptoms are attributed to the release of neuropeptides from the sensory corneal terminals (e.g., SP and CGRP).

5.03.3.2.2 *Electron microscopy*

Electron microscopic studies showed that thin fibers entering the epithelium lost their Schwann cell covering, often branched and exhibited varicosities that contained mitochondria, neurofilaments and round clear vesicles (Figures 10 and 11; Belmonte, C. and Gallar, J., 1996; Müller, L. J. *et al.*, 1996). Terminals containing granular vesicles were numerous only at the limbus of the cornea. These endings disappeared after sympathectomy and, therefore, were considered to be adrenergic terminals. Sensory endings (i.e., those having their somata in the trigeminal ganglion) were often ir to SP and CGRP. Hoyes A. D. and Barber P. (1976) distinguished between two types of sensory free nerve endings that originated from unmyelinated corneal fibers:

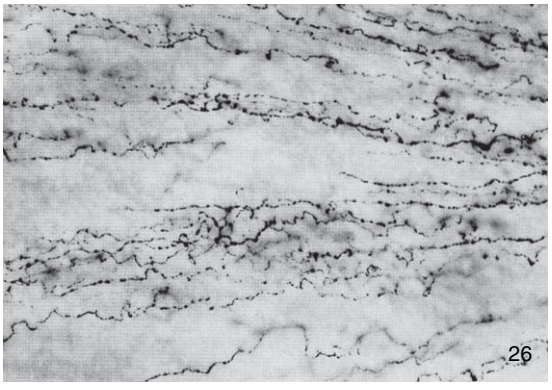

Figure 10 Flat mount preparation of cornea. The focal plane is through the base of the corneal epithelium, which is heavily innervated by varicose calcitonin gene-related peptide-immunoreactive (CGRP-ir) axons coursing radially inward from the limbus. Branches can be traced in more superficial focal planes ascending perpendicularly between epithelial cells to approach the epithelial surface (×200). (From Silverman, J. D. and Kruger, L., 1988, with permission.)

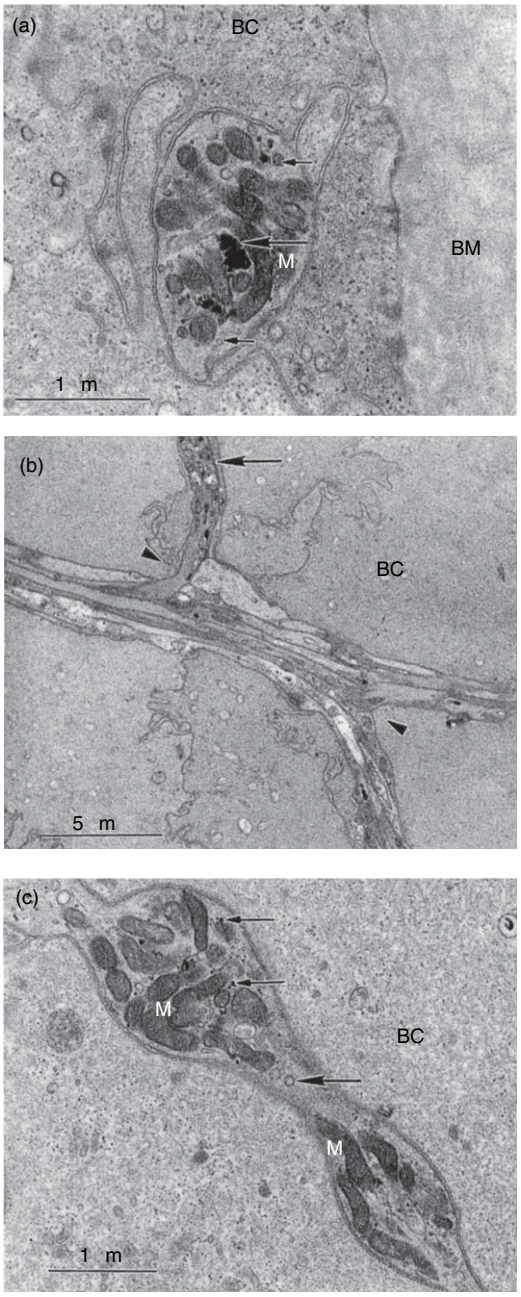

Figure 11 Nerve fibers in the epithelium of the human cornea. (a) Cross section of a single nerve fiber at the level of an axonal expansion (a bead), showing numerous mitochondria (M), glycogen particles (large arrow), and vesicles (small arrow) (×16576). (b) Frontal section of a nerve filament that bifurcates at the points indicated by the arrowheads. The single fiber running in the upper part of the picture has a bead filled with mitochondria (large arrow) (×3000). (c) Frontal section of a single fiber, showing two beads filled with numerous dark mitochondria (M), glycogen particles (small arrows), and vesicles (large arrow) (×12544). BC, basal cell; BM, Bowman's membrane. (From Müller, L. J. *et al.*, 1996, with permission.)

(1) Units that contained many mitochondria and were considered to be mechano- or thermoreceptors.
(2) Units exhibiting clear and dense-core vesicles. These units were assumed to be nociceptive afferents; they were concentrated in the central parts of the cornea where no blood vessels are present. The majority of this fiber type had an intraepithelial location.

Attempts to correlate morphology with function in corneal receptive endings did not yield unequivocal results. Therefore, in their review, Belmonte C. and Gallar J. (1996) stated that "no morphological specialization has been found in corneal nerve terminals associated with the various functional classes of corneal afferents."

5.03.3.3 Deep Somatic Tissues

5.03.3.3.1 Muscle pain compared to cutaneous pain

Muscle pain is less well localized than cutaneous pain. One reason for this difference may be the fact that muscle pain – but not cutaneous pain – is often referred to sites distant from the lesion. Another possible reason is the lower innervation density of muscle tissue. Direct quantitative comparisons between the innervation density of muscle and skin have not been published so far and are difficult to make, because muscle tissue is 3D and skin largely 2D.

Free nerve endings in muscle are partly nociceptive and partly nonnociceptive. The latter ones have a low mechanical threshold and are assumed to mediate pressure and tension sensations from muscle tissue. Another important function for these nonnociceptive endings in muscle is to control the adjustment of circulation and respiration to the requirements of muscle work. They are activated by physiological degrees of exercise and send their information to the circulatory and respiratory centers in the medulla (McCloskey, D. I. and Mitchell, J. H., 1972).

5.03.3.3.2 Nociceptors in muscle and tendon

Several studies on the response properties of unmyelinated afferent fibers from cat and dog muscle demonstrated that a subpopulation of these afferents are excited by stimuli (strong mechanical and algesic chemical) that are known to elicit pain (Kumazawa, T. and Mizumura, K., 1977; Mense, S., 1977; Mense, S. and Meyer, H., 1985).

Besides capsaicin, ATP (binding to the purinergic P2X3 receptor), NGF, and protons (acting through TRPV1 and acid-sensing ion channels (ASICs)) are effective stimulants for muscle nociceptors (Hoheisel, U. *et al.*, 2004; 2005). Similar to nociceptive afferents from the skin, afferent fibers from nociceptors in rat muscle are equipped with TTX-resistant (TTX-r) Na^+ channels (Steffens, H. *et al.*, 2003).

5.03.3.3.2.(i) Light microscopy In a quantitative evaluation of neuropeptide-ir free nerve endings and preterminal axons (both characterized by varicosities) in the gastrocnemius–soleus muscle of the rat, most endings were found around small blood vessels (arterioles or venules), whereas capillaries and the muscle cells were not supplied by these endings. Most numerous were the CGRP-ir endings followed by endings with SP-immunoreactivity (IR), VIP-IR, NGF-IR, and GAP-43-IR (Reinert, A. *et al.*, 1998). Many endings exhibited IR for more than one peptide, e.g., for SP and CGRP or SP and VIP (Figure 12).

After 12 days of an experimental myositis, the innervation density of the muscle with neuropeptide-ir free nerve endings was significantly increased. The effect was particularly marked for endings with SP-IR, GAP-43-IR, and NGF-IR (Reinert, A. *et al.*, 1998; Figure 13 (b and c)). The density of the SP-ir fibers doubled in inflamed muscle. Of course the question arose if this increase was due to inflammation-induced sprouting of the nerve fibers or due to an increase in the neuropeptide content of the individual fiber so that a higher proportion of fibers were above the detection threshold in the fluorescence microscope. The finding that the density of NGF-ir and GAP-43-ir fibers increased together with that of SP-ir endings was interpreted that sprouting had occurred, because NGF and GAP-43 are strongly expressed in growth cones.

Free nerve endings in the calcaneal tendon of the rat showed IR to the same neuropeptides, but the distribution of the fibers was different from muscle. In the epitendineum, the fibers formed a much denser network than in muscle, but the collagen fiber bundles in the center of the tendon were largely free from free nerve endings (Reinert, A. and Mense, S. unpublished data). This finding may explain why chronic mechanical stress to the epitendineum can be very painful, whereas ruptures of collagen bundles within the tendon may occur without pain.

5.03.3.3.2.(ii) Electron microscopy

5.03.3.3.2.(ii).(a) Muscle The first comprehensive report on the morphology of free nerve endings

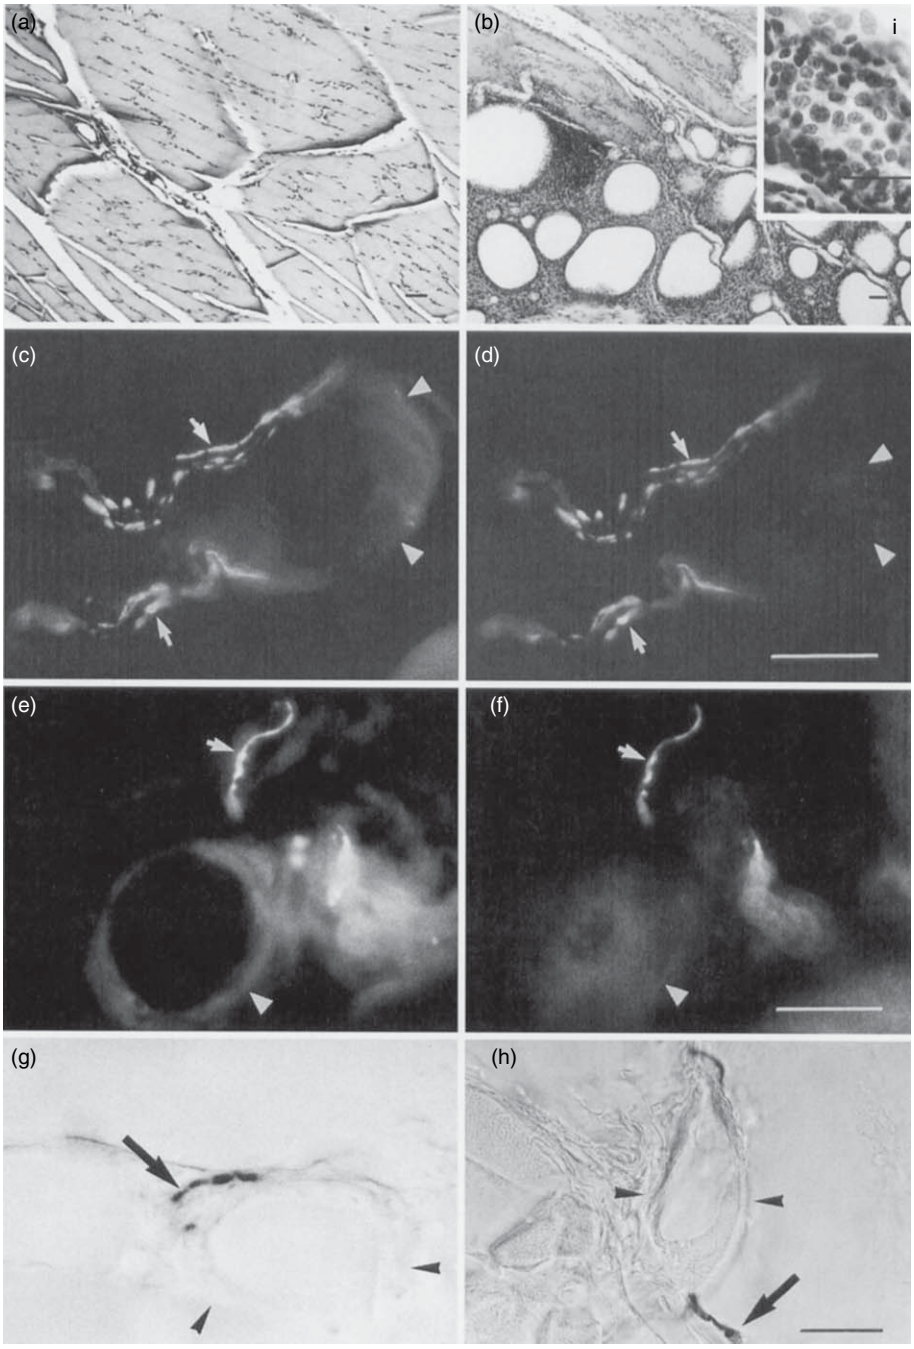

Figure 12 (a and b) Sections of intact (a) and persistently inflamed (b) muscle. Scale bar = 100 μm. The insert (i) in (b) shows lymphoid cells between vacuoles at a higher magnification. Scale bar = 50 μm. (c–f) Neuropeptide-ir nerve fibers in muscle. (c) Varicose SP-ir fibers (arrows) in the adventitia of an artery (arrowheads). (d) The fibers shown in (c) double-labeled for calcitonin gene-related peptide (CGRP). (e) Perivascular SP-ir fiber that is also ir for vasoactive intestinal polypeptide (VIP; (f)). (g) Perivascular fiber in inflamed muscle exhibiting immunoreactivity for NGF (arrow, same magnification as in (h)). (h) Growth-associated protein 43 (GAP 43)-ir fiber (arrow) in the wall of an artery (arrowheads). Scale bar = 25 μm (c–h). (From Reinert, A. *et al.*, 1998, with permission.)

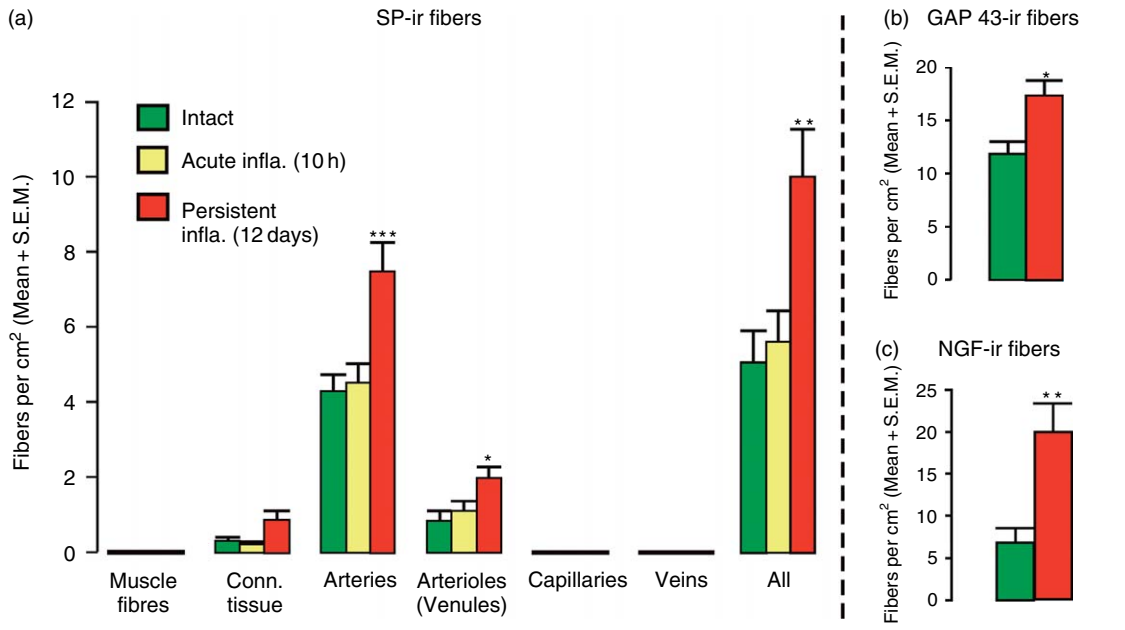

Figure 13 Innervation density of substance P-immunoreactive (SP-ir), growth-associated protein 43 (GAP 43)-ir, and nerve growth factor (NGF)-ir fibers in intact and inflamed muscle. Acute inflammation (yellow bars), duration 10 h; persistent inflammation (red bars), duration 12 days. (a) Distribution of SP-ir fibers in the components of muscle tissue. Note that no fibers were found close to muscle fibers and capillaries. Asterisks mark the level of significance compared to intact muscle. $^{*}p < 0.05$; $^{**}p < 0.01$; $^{***}p < 0.001$, *U* test. (Modified after Reinert, A. *et al.*, 1998.)

in skeletal muscle of the cat was published by Stacey M. J. (1969). He used the silver impregnation technique in sympathectomized animals and focused on endings supplied by group III and IV fibers. The majority of the latter had a diameter of 0.35 µm; the unmyelinated afferents outnumbered the myelinated ones by a factor of 2. A prominent location of free nerve endings supplied by group IV fibers was the adventitia of arterioles and venules. Myelinated (group II and III) afferents generated not only free nerve endings but also paciniform corpuscles, whereas unmyelinated fibers terminated exclusively in free nerve endings.

In another study on sympathectomized cats, von Düring M. and Andres K. H. (1990) reported that the predominant location of group III and IV endings was in the perimysium surrounding larger or smaller bundles of muscle fibers. Other locations were the adventitia of arterioles, venules, and lymphatic vessels (LV), and finally the endoneurium of nerve fiber bundles. The latter terminals were assumed to belong to nervi nervorum. In muscle, the terminals of group III fibers were generally larger than those of group IV fibers, and they contained more mitochondria and a more distinct receptor matrix. Figure 14 shows a group IV terminal in the endomysium around the precapillary segment of a blood vessel in the soleus muscle. The ending contained clear and dense-core vesicles and had exposed membrane areas. The authors suggested that those terminals (mainly originating from group III fibers) that had a close association with connective tissue may have a mechanoreceptive function mediating stretch or pressure, whereas endings that lacked this feature but had a spatial relation to mast cells were nociceptors.

5.03.3.3.2.(ii).(b) Tendon The electron microscopic reconstruction of free endings in the calcaneal tendon of the cat yielded various morphological types of free nerve endings connected to group III and IV afferent fibers (Andres, K. H. *et al.*, 1985). Based on morphological criteria or the location in the tissue, the authors distinguished five types of free nerve endings supplied by group III fibers: Type 1 terminated in venous vessels (VV) (called the lanceolate type); it was special in that it had a flattened profile in cross sections and possessed exposed receptive areas on its edges. Type 2 ended in the wall of LV. Types 3 and 4 supplied the connective tissue around blood vessels, and one of these types had contacts to collagen fiber bundles. The collagen bundles were assumed to transfer mechanical forces to

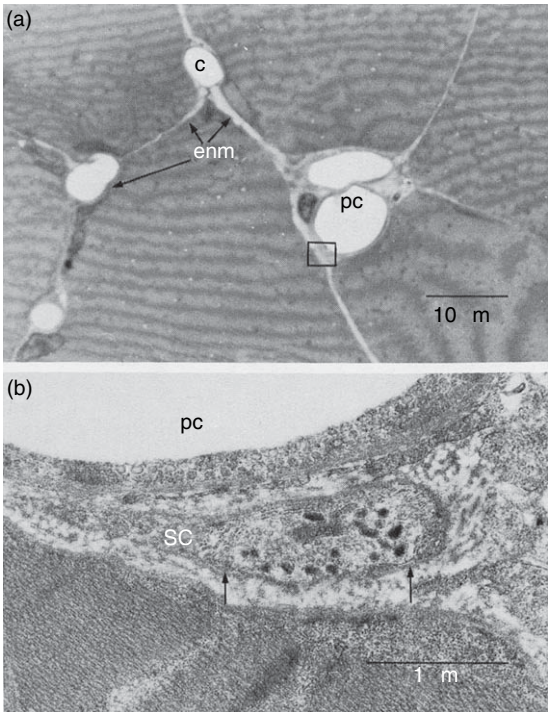

Figure 14 Nerve terminal of a group IV fiber in the soleus muscle of the cat. Rectangle in (a) represents the area of the receptor shown in (b). The terminal axon contains numerous dense-core and clear vesicles. pc, precapillary segment; c, capillary; SC, Schwann cell. Arrows indicate exposed axonal membrane areas. (From von Düring, M. and Andres, K. H., 1990, with permission.)

the receptive ending and, therefore, the endings were viewed as mechanoreceptors. The fifth type of group III ending innervated the endoneural connective tissues of small nerve fiber bundles (Figure 15).

In the same study, two types of free nerve endings of group IV fibers were described; both were located in the connective tissue of blood vessels, and some of the fibers contained granulated vesicles. The terminals showed penicillate formations (Figure 16).

5.03.3.3.3 Nociceptors in joints and ligaments

5.03.3.3.3.(i) Pain from joints In humans, experimental joint pain has been evoked by administration of noxious mechanical and chemical stimuli to the articular capsule and ligaments. No pain is elicited by stimulation of cartilage, because cartilage is not innervated. Joint inflammation is characterized by hyperalgesia and persistent pain at rest. The discharge properties of joint nociceptors largely reflect these subjective phenomena of joint pain (Guilbaud, G. *et al.*, 1985; Schaible, H.-G. and Schmidt, R. F., 1985; Schaible, H.-G. and Grubb, B. D., 1993; Schaible, H.-G., 2006). In inflamed joint, initially mechanoinsensitive afferents (silent nociceptors) are sensitized and may become mechanosensitive (Schaible, H.-G. and Schmidt, R. F., 1988).

5.03.3.3.3.(ii) Ultrastructure of articular free nerve endings In a thorough investigation of articular endings, Heppelmann B. *et al.* (1990a) studied free nerve endings from the knee joint of the cat in sympathectomized animals. Figure 17 shows the reconstruction of group III and IV nerve endings from the joint capsule of the cat's knee joint. As in other tissues, free nerve endings in joint were ensheathed by Schwann cells, and only some sites were not covered. Usually, these exposed areas were located in the varicosities of the ending (the beads) and the end bulb, here the axon, often directly abutted the basal lamina. The exposed membrane areas were assumed to be the receptive sites of the fibers; they exhibited structures that are often associated with receptive sites: aggregates of mitochondria, glycogen particles, vesicles in the axoplasm, and an electron-dense filamentous structure of the axoplasm (the receptor matrix). The end bulb, i.e., the most distal beaded end of the fiber (Figure 18 shows the end bulb of one branch of the group III unit reconstructed in Figure 17), had generally the same structure as the axonal beads, except that the mitochondria showed a special arrangement: the organelles were not oriented in parallel as in the axonal beads but pointed with their axis in all possible directions.

In the cat's knee joint capsule, free nerve endings generated by group III fibers were smaller in axon diameter and had shorter branches (up to 200 μm) than those supplied by group IV fibers (more than 300 μm). The main difference between group III and IV endings was that the latter never had a neurofilament core in their axoplasm, which was present in all axons and axonal beads of group III fibers (but not in the end bulbs). The functional significance of the neurofilament core is obscure; one possible function is mechanical stabilization of the group III endings that usually have a more unfavorable quantitative relation between the fluid axoplasm and the more rigid axolemma.

The authors of these and similar data (Heppelmann, B. *et al.*, 1990a; 1990b; Messlinger, K., 1996) put forward the concept that both group III and IV fibers form sensory terminal trees that consist of the preterminal axon and its branches (Figure 5). The

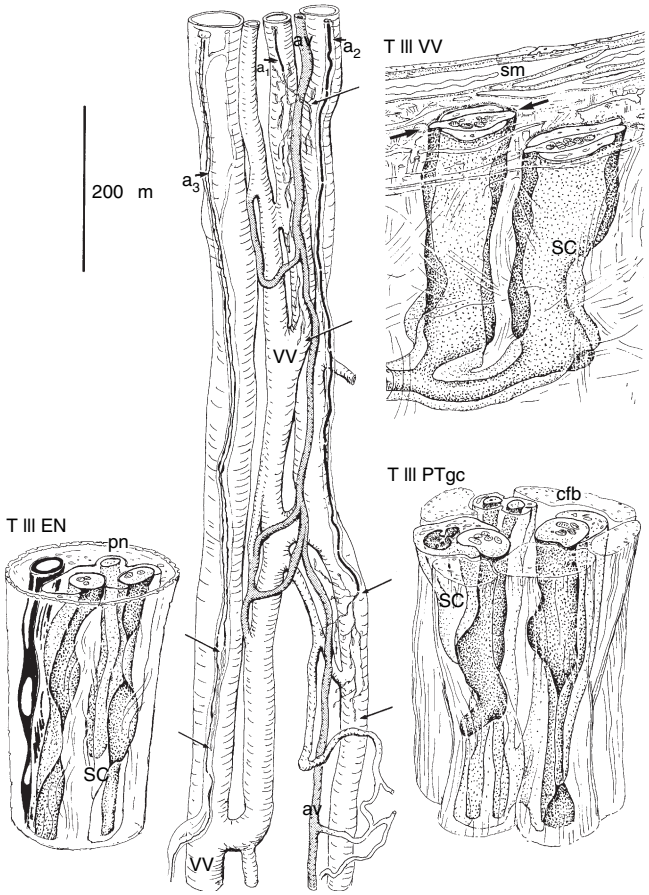

Figure 15 Group III fiber terminals in cat calcaneal tendon. Reconstruction of a series of sections over a length of 1 mm showing three different terminals of group III afferents. A fascicle of arterial vessels (av) and venous vessels (VV) with some arterio-venous anastomoses is accompanied by small nerve fiber bundles of which the myelinated axons (a_1, a_2, a_3) are reconstructed. The schematic drawings show segments of three different terminals at a higher magnification (T III VV, T III PTgc, and T III EN) with their typical relations to the surrounding tissue structures. Axon membrane segments without any Schwann cell (SC) covering are marked by higher contrast. The terminal of the a_1 axon is the T III VV type with two lanceolate terminals in the adventitia of the vessel. The arrows indicate the free edges of the terminal. Smooth muscle cell (sm). The terminal of the a_2 axon is type T III PTgc in the connective tissue of the vessel–nerve–fiber fascicle. The terminals are oriented to collagen fiber bundles (cfb). The terminal of the a_3 axon is the T III EN type. The terminals ramify within the endoneural space. Another small myelinated axon passes the terminals. Perineural sheath (pn). The length of the receptive areas of each myelinated axon is indicated in the reconstruction by arrows. (From Andres, K. H. *et al.*, 1985, with permission.)

terminal tree is not covered by myelin (in group III endings) and lacks a perineurial sheath (in both group III and IV endings); it is assumed to form the sensory ending proper.

Considerations on the space constant of free nerve endings prompted Heppelmann B. *et al.* (1990a; 1990b) to hypothesize that the distance from the end bulb as the main receptive region to the regenerative region – where the action potential originates – may be dangerously great for a safe transformation of the receptor potential into an action potential. Therefore, the axonal beads may not only serve as receptive sites but also as amplifiers of the receptor potential.

The group IV endings terminating in the medial collateral ligament (Figure 19) exhibited the same features as the terminals in the joint capsule: They had exposed membrane areas and contained mitochondria, glycogen particles, and vesicles (Heppelmann, B. *et al.*, 1990b; Messlinger, K., 1996).

Group III and IV fibers of the joint terminate as free nerve endings in the fibrous capsule, adipose tissue, ligaments, menisci, and periosteum. Staining

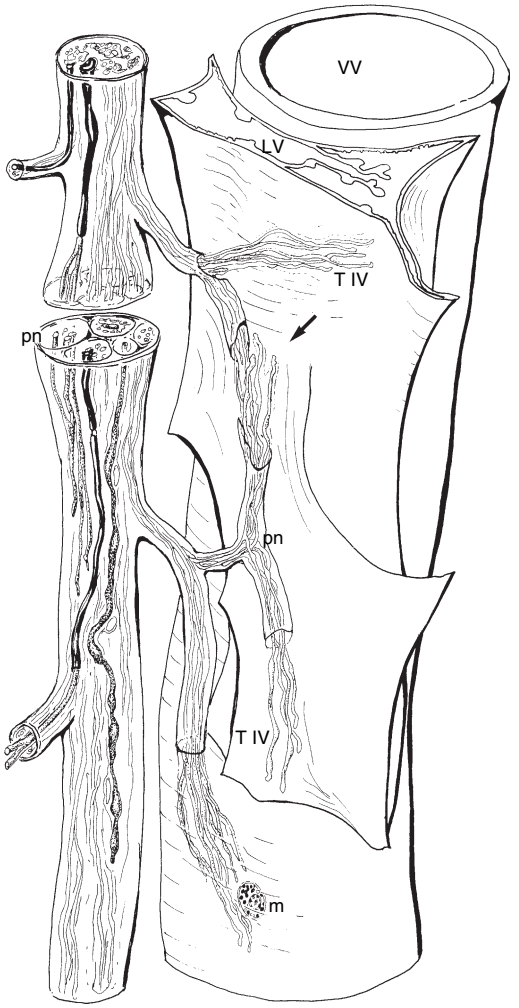

Figure 16 Group IV fiber terminals (T IV) in cat calcaneal tendon. Schematic drawing of group IV fibers and their sensory regions in the surrounding connective tissue of venous (VV) and lymphatic (LV) vessels. Perineural sheath (pn). The various parts of the scheme are not to scale. The terminal bundles end in penicillate formations. (From Andres, K. H. *et al.*, 1985, with permission.)

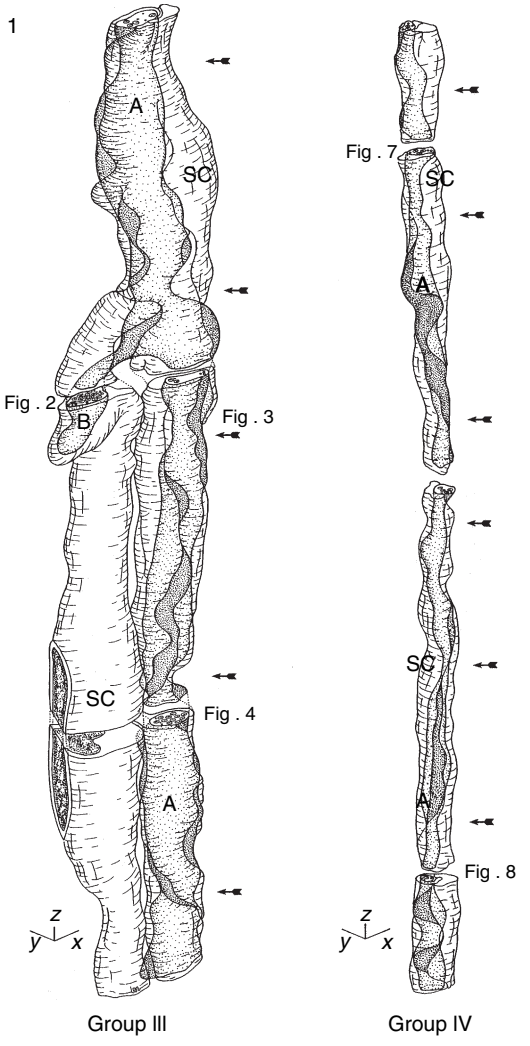

Figure 17 Sensory endings in the knee joint capsule of the cat. Reconstructions based on ultrathin sections at 1-μm intervals. Areas of bare axolemma without Schwann cell covering are marked by dense stippling. A, sensory axon; SC, Schwann cell; arrows, thin segments between axonal beads (×6000). *x*, *y*, *z* bars, 1 μm. *Left*: group III fiber, length of reconstructed fiber 70 μm. *Right*: group IV fiber. The axonal beads are shorter and the thin segments longer than in group III fibers. Areas of bare axolemma are interrupted by axon segments with complete Schwann cell wrapping. (From Heppelmann, B. *et al.*, 1990b, with permission.)

for nerve fibers and neuropeptides also demonstrated endings in the synovial layer. Interestingly, a few group IV endings terminated in the perineurium (PN) of the articular nerve. Assuming that these endings are nociceptors, they might be responsible for neuropathic pain originating in the joint.

The major neuropeptides in small-diameter joint afferents were SP, CGRP, and somatostatin (SOM). Neurokinin (NK)-A, galanin, enkephalins, and neuropeptide Y have also been localized to joint afferents (Schaible, H.-G. and Grubb, B. D., 1993; Schaible, H.-G., 2006).

5.03.3.3.4 Tooth pulp

5.03.3.3.4.(i) Toothache In psychophysiological studies, electrical stimulation of the tooth pulp has been reported to elicit pain exclusively (Andersson, S. A. *et al.*, 1973). Therefore, the free nerve endings in the pulp were assumed to be either nociceptors or sympathetic postganglionic fibers. Rats show aversive behavior when capsaicin is applied to the exposed

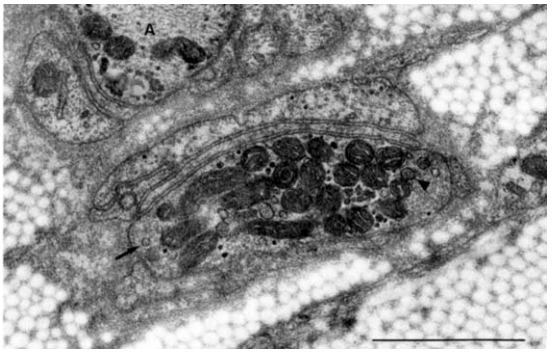

Figure 18 Axonal end bulb of an articular group III fiber in the cat. In addition to mitochondria and glycogen particles, the end bulb contains several clear vesicles (arrow) and larger dense-core vesicles (arrowhead). In contrast to more proximal axonal beads, microtubules and a neurofilament core are missing in the end bulb. (From Heppelmann, B. *et al.*, 1990a, with permission.)

dentine of the incisors (Chidiac, J. J. *et al.*, 2002; Rifai, K. *et al.*, 2004). The latter observation indicates that nociceptive afferents of the tooth pulp are equipped with the TRPV1 receptor for which capsaicin is a specific ligand.

Functional studies of the receptive properties of single unmyelinated tooth pulp afferents are scarce. The published data show that slowly conducting afferent units from cat are sensitive to stimuli that are known to elicit pain in humans (hot and cold, local administration of bradykinin (BK), and mechanical stimulation) (Jyväsjärvi, E. and Kniffki, K. D., 1992). Many of the recorded units responded to more than one stimulus and thus behaved like polymodal nociceptors. In another study, the sensitivity to capsaicin of Aβ-, Aδ-, and C-fibers was compared in cat tooth pulp afferents. Not only C-fiber endings were excited but also Aδ-units, albeit at a smaller proportion. None of the Aβ-endings responded to the stimulant (Ikeda, H. *et al.*, 1997).

No studies combining electrophysiological and morphological techniques were conducted on teeth. Therefore, in morphological investigations a possible nociceptive function of the free nerve endings can be discussed, but is not sure.

5.03.3.3.4.(ii) Light and electron microscopy

Data are available from many species including man. The morphology of the free nerve endings is similar to that described above for other tissues in more detail. In the following paragraph, possible differences between nerve fibers in mature and continuously growing teeth (e.g., mice incisors) are not considered.

(1) The great majority (56–79.6% in the cat mandibular canine tooth; Holland, G. R. and Robinson, P. P., 1983) of the fibers supplying the tooth pulp are unmyelinated with a mean diameter of 0.4 μm in man (Koling, A., 1985); they often branch and form a dense subodontoblastic plexus (the peripheral plexus of Raschkow, see Byers, M. R., 1984, for review) in the apex of the tooth. Between the plexus and the odontoblast layer, there is the cell-free zone of Weil. Figure 20 shows an overview of the afferent fibers in the root and coronal pulp of a rat molar. The data were obtained in experiments in which the trigeminal ganglion was injected with an anterogradely transported marker (WGA-HRP) to visualize afferent fibers only (Ibuki, T. *et al.*, 1996). In the subodontoblastic region, axo-axonal appositions and appositions between axons and odontoblasts have been described by some authors, but others could not support this finding. The other pulpal afferents conduct in the Aδ-range; Aβ-fibers are sparse.

(2) Many axons are incompletely ensheathed by Schwann cells (Figure 21); they sometimes leave the Schwann cell sheath completely to terminate as naked axons in the extracellular space. In those fibers that do have a sheath, the Schwann cells often lack a basal lamina (Figure 22; Byers, M. R. *et al.*, 1982). The majority of the afferent fibers form beaded free nerve endings in odontoblast layer, predentin, and in dentinal tubules, many of which are innervated. The intradentinal endings extend only 100–200 μm into the dentin, and sometimes more than one axon accompanies an odontoblast process (Figure 23). Gunji T. (1982) put forward the concept that the odontoblast processes and the axons in the dentinal tubules form a mechanoreceptive complex. In contrast to the intradentinal axons, the odontoblast processes reach the dentin–enamel border and could be deformed by mechanical stimuli. The mechanical movements or deformations of the processes may then excite the sensory axons that do not penetrate that far into the dentinal tubules.

(3) The varicosities of the free nerve endings exhibited specializations known from nociceptors in other tissue such as mitochondria, small clear and large dense-core vesicles, smooth endoplasmic reticulum, and few microtubules and neurofilaments (Figure 24; Byers, M. R., 1984; Ibuki, T. *et al.*, 1996). Ibuki T. *et al.* (1996) distinguished between

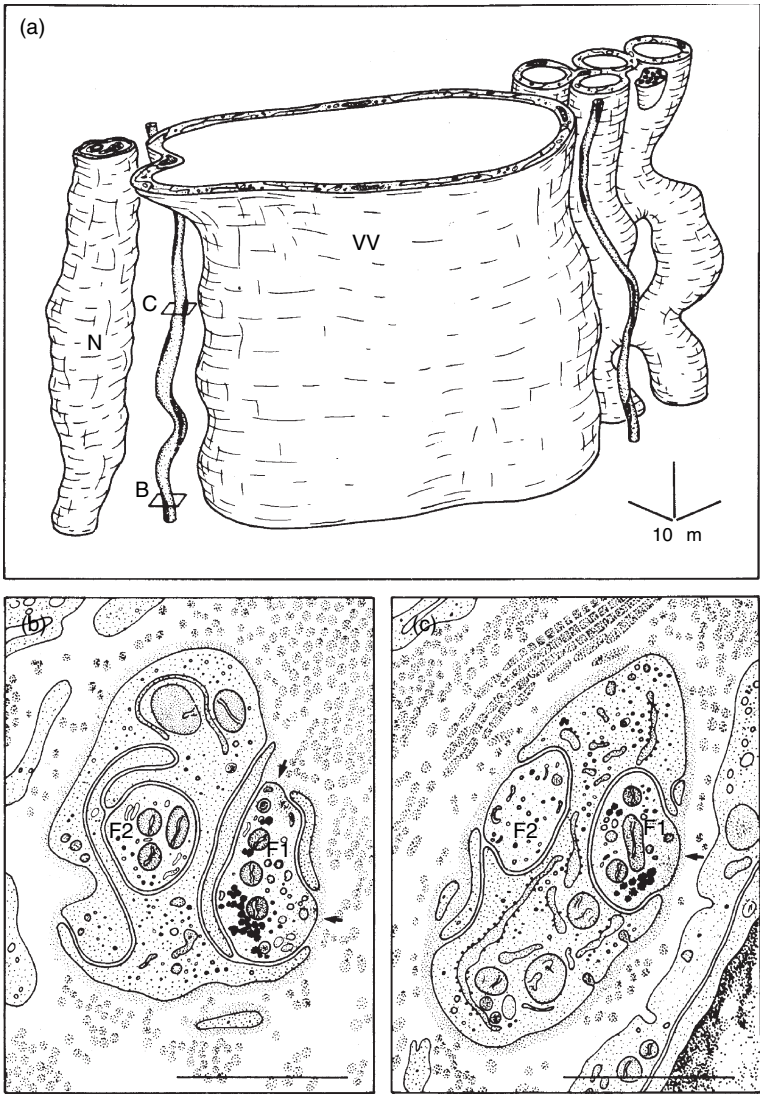

Figure 19 Group IV fiber endings at a venous vessel (VV) in the medial collateral ligament of the cat. (a) Reconstruction based on serial semi- and ultrathin sections. Besides a small peripheral nerve (N), two terminal nerve fiber bundles without perineurial sheath that enclose two group IV fibers (*left*) and one single fiber (*right*) run along the VV. (b and c) Cross sections of the nerve fiber bundle with two group IV fibers as marked in Figure 3(a) at high magnification. Drawings from original electron micrographs. Scale bar = 1 μm. (b) Cross section showing a bulge of one of the nerve fibers (Fl) with bare areas of the axolemma (arrows), mitochondria, glycogen particles, and vesicles. The other nerve fiber (F2) is completely ensheathed by the Schwann cell. C, cross section 40 μm distal from that of Figure 3(b) showing the final thickening of the nerve fiber Fl with bare area of axolemma (arrow). The second nerve fiber (F2) continues. (From Heppelmann, B. *et al.*, 1990b, with permission.)

two types of varicosity: one contained many mitochondria, while the other was characterized by the presence of large dense-core and small clear vesicles. Generally, a rich supply with mitochondria and glycogen particles is interpreted as an indication of high energy demands and, therefore is likely to occur in endings with a low mechanical threshold and high firing probability, while nociceptive endings have a lower probability of being excited, and therefore need less mitochondria.

(4) Besides a nociceptive function many of the small-caliber tooth afferents may have a trophic influence on blood vessels in the pulp or on odontoblasts. They may be necessary for repair or normal growth, as in continuously growing teeth. The finding that the anterograde marker

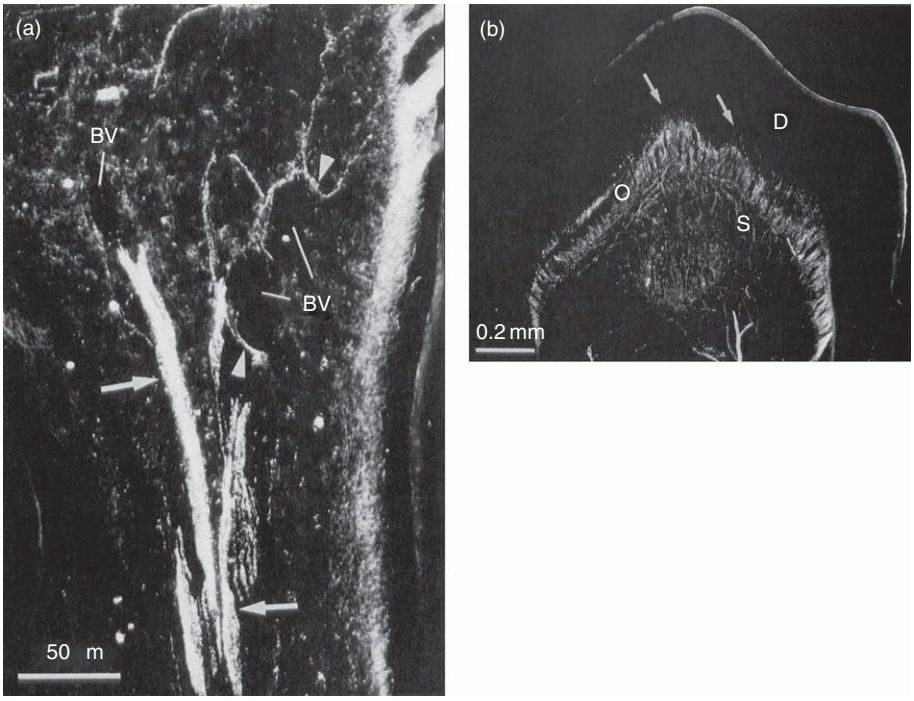

Figure 20 Innervation of root pulp (a) and coronal pulp (b) in a rat tooth. The fibers were labeled anterogradely from the trigeminal ganglion. (a) Bundles of labeled fibers (arrows) run along the blood vessels (BV) of the root pulp. Some fibers surround the blood vessels (arrowheads). (b) The fibers form a subodontoblast plexus (S) and penetrate the dentin (arrows). D, dentin; O, odontoblast. (From Ibuki, T. *et al.*, 1996, with permission.)

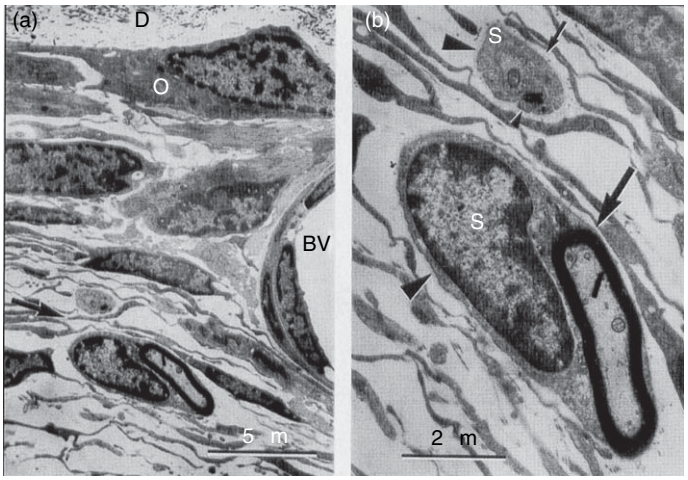

Figure 21 (a) Fibers labeled anterogradely with horseradish peroxidase in the subodontoblastic region of the tooth. BV, blood vessel; D, dentin; O, odontoblast. (b) High magnification of the area marked by an arrow in (a). Horseradish peroxidase reaction product is present in the myelinated Aδ-axon (large arrow) and unmyelinated axons (small arrow). The unmyelinated axon has partially lost its Schwann cell sheath (arrowheads). S, Schwann cell. (From Ibuki, T. *et al.*, 1996, with permission.)

(WGA-HRP) injected into the trigeminal ganglion by Ibuki T. *et al.* (1996) was found not only within the axons but also outside between the axons and the odontoblast processes (Figure 24) was assumed to reflect a release process that normally supplies the odontoblasts with trophic substances. This hypothesis resembles the nocefector concept of Kruger.

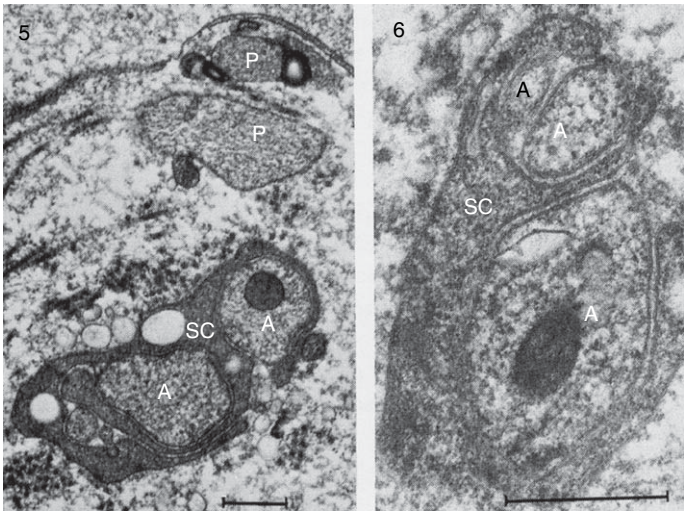

Figure 22 Nerve fibers in the cell-free zone of the tooth pulp. Unmyelinated axons (A) were identified in this zone when surrounded by a Schwann cell (SC), but no basal lamina accompanied the Schwann cell. Other cell processes (P) could be axons or fibroblasts. Scale bars, 0.5 μm (×42300). (From Byers, M. R. *et al.*, 1982, with permission.)

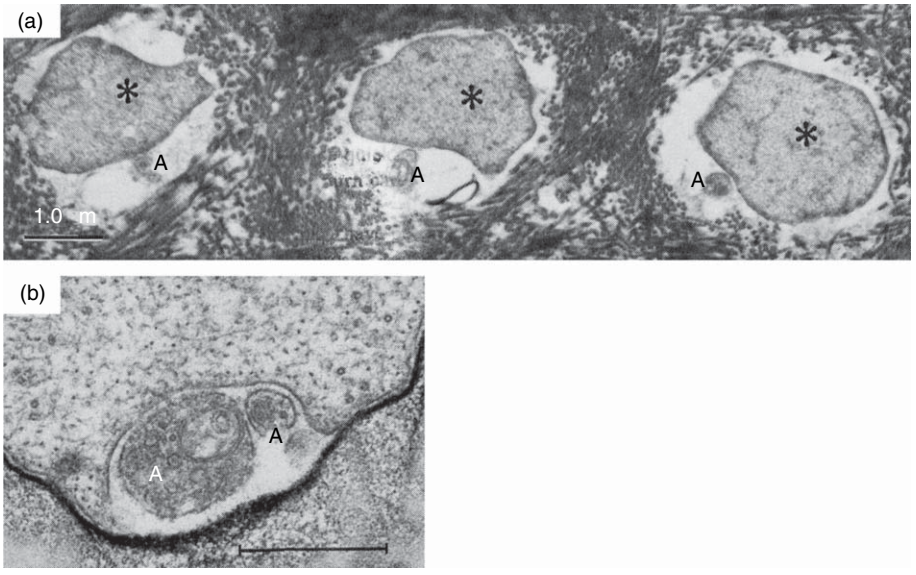

Figure 23 Axons in dentinal tubules. (a) A cluster of adjacent dentinal tubules at the predentin–dentin border. Each tubule contains an axon (A) and an odontoblast process (*) (×10350). (b) Two adjacent axons in the same dentinal tubule. (From Byers, M. R. *et al.*, 1982, with permission.)

5.03.3.3.4.(iii) Neuropeptide content and equipment with receptor molecules Sensory dental axons contain many neuropeptides (SP, CGRP, VIP, enkephalin), the most interesting one being SP because of its relation to a nociceptive function. A particularly rich innervation with CGRP-ir fibers was found in the subodontoblast layer and the dentinal tubules (Kruger, L. and Halata, Z., 1996). These endings were thought to have a noceffector function (Kruger, L., 1988).

SP-ir fibers predominated in the center of the tooth pulp. The expression of SP in carious human teeth has been found to be increased, and the increase was larger in symptomatic than in asymptomatic teeth. This finding parallels the results obtained from inflamed muscle (see above) and suggests that

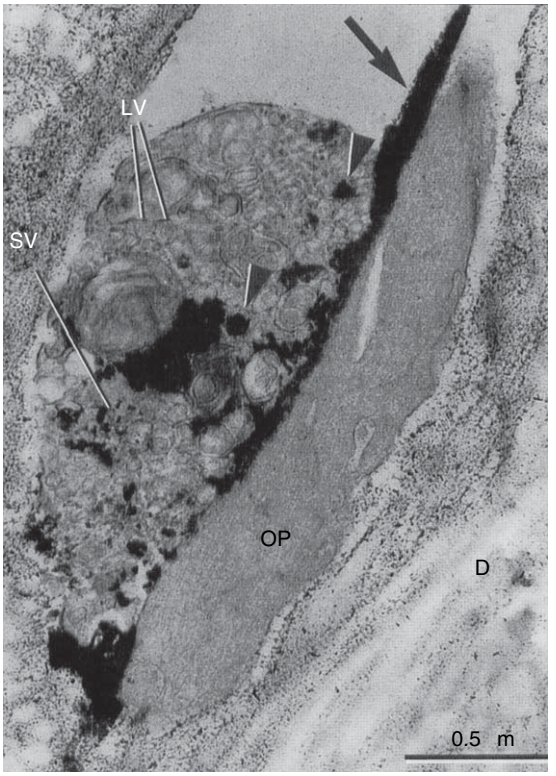

Figure 24 Anterogradely labeled sensory varicosity adjacent to an odontoblast process (OP) in dentin. The varicosity is full of large dense-core vesicles (LV) and small clear vesicles (SV). Some vesicles (arrowheads) contain the horseradish peroxidase reaction product used for anterograde labeling. The reaction product is also present in the extracellular space (arrow). D, dentin. (From Ibuki, T. *et al.*, 1996, with permission.)

SP plays an important role in the mediation of toothache (Rodd, H. D. and Boissonade, F. M., 2000). In one patient with hereditary sensory and autonomic neuropathy, CGRP- and SP-ir fibers were completely missing, which could explain the sensory deficit associated with this condition (Rodd, H. D. *et al.*, 1998). The lack of CGRP- and SP-ir fibers was accompanied by an upregulation of neuropeptide Y.

The nerve endings in the tooth pulp have been shown to be equipped with receptor molecules that are thought to be associated with a nociceptive function, e.g., P2X3, TRPV1 (Renton, T. *et al.*, 2003), and the vanilloid receptor-like protein, VRL1. In rat molar tooth pulp, fibers ir to trkB (the receptor for BDNF and NT-4) were found. These fibers included both unmyelinated and myelinated units. This and other findings were interpreted as indicating that BDNF and/or NT-4 are involved in the development, differentiation, or regeneration of the tooth pulp innervation (Foster, E. *et al.*, 1995).

However, not all free nerve endings can be considered to be nociceptive; in the tooth pulp many endings appear to supply blood vessels (Zhang, J. Q. *et al.*, 1998). The vascular innervation with neuropeptide-ir nerve endings is largely restricted to arterioles; capillaries and lymphatics were mostly devoid of an innervation. This distribution pattern resembles that of skeletal muscle. Substances involved in the vascular and cellular regulation of the tooth pulp in the rat are SP, NK-A, and CGRP, which are thought to be released from nerve endings. This function was inferred from the finding that pulpal hard tissue cells, blood vessels, and fibroblasts were equipped with NK-1 and NK-2 receptors (for SP and NK-A, respectively) as well as CGRP1 receptors (Fristad, I. *et al.*, 2003).

5.03.3.3.5 Dura mater encephali

5.03.3.3.5.(i) Headache Generally, those types of headache that are associated with vascular changes in the meninges (e.g., migraine) are being attributed to the activation of para- or perivascular nociceptive endings by agents released from the nerve terminals. Among these substances are SP, CGRP, and NK-1. Observations supporting this assumption are that – when tested in awake subjects – meninges are most painful close to blood vessels, and that migraine pain is most intense during the phase of vasodilatation and increase of vascular permeability.

5.03.3.3.5.(ii) Light and electron microscopy In their light and electron microscopic study on receptive endings in the dura mater of the rat, Andres K. H. *et al.* (1987) described terminals of myelinated and unmyelinated fibers. The tissue around postcapillary blood vessels and the superior sagittal sinus exhibited a particularly high innervation density of endings. Contrary to former belief, the dura also contained LV (Figure 25). These vessels were innervated mainly by endings from unmyelinated fibers.

Some of the myelinated fibers terminated in Ruffini-like nerve endings, while most of the myelinated and all of the unmyelinated fibers terminated in free nerve endings. The Ruffini-like receptors were located close to collagen fiber bundles of the wall of the sagittal sinus and of other blood and LV. They were viewed as stretch receptors.

Among the free nerve endings formed by unmyelinated fibers, one type was located very close (at a distance of $<1\,\mu m$) to the endothelial cells of the

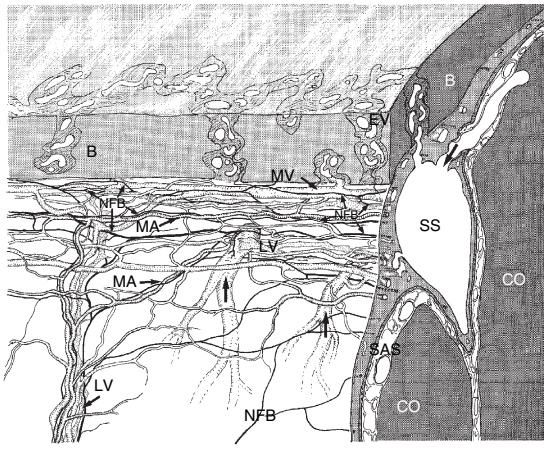

Figure 25 Vascular bed of the dura underneath the parietal bone (B) and dorsal to the sagittal sinus (SS). Arrows, entrance of the superior cerebral veins into the sagittal sinus; MA, branches of meningeal artery; MV, branches of meningeal vein; EV, emissary vein; LV, lymphatic vessels; NFB, nerve fiber bundles exhibiting a terminal plexus; CO, cortex; SAS, subarachnoidal space. postcapillary venules. It had the typical appearance of free nerve endings in other tissues with exposed membrane areas, mitochondria, vesicles, and a receptor matrix. The endings that were located close to the wall of blood vessels would be in a good position to monitor the composition of the interstitial fluid in the vicinity of the vessels (Figure 26). They could well perform nociceptive functions, for instance in cases of headache when sensitizing and pain-producing substances are released from the blood plasma and afferent nerve fibers.

Many of the nerve fibers accompanying blood vessels contained CGRP or SP (Figure 27; Hanesch, U., 1996). Like in other tissues, SP-ir fibers were less numerous than CGRP-ir ones. While SP-IR was located inside the axoplasm, the SP receptor NK-1 was found on the outer membrane of the Schwann cells surrounding the axons.

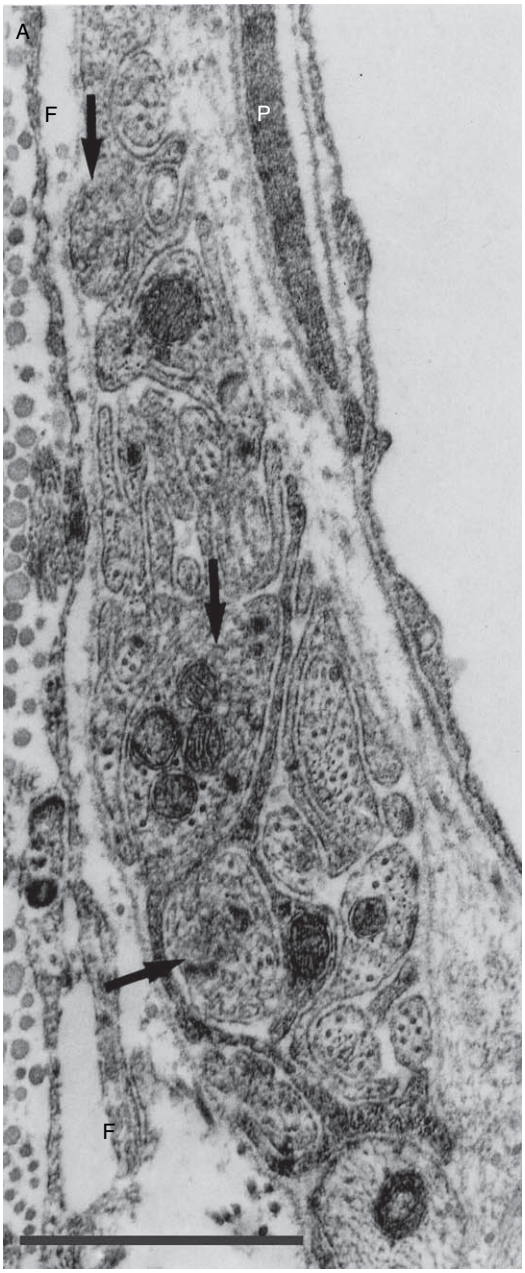

Figure 26 Nerve terminations in the dura at the wall of a venous vessel. Axon profiles with vesicles and receptor matrix are indicated (arrows); the other axons exhibit cytoskeletal elements (×45000). Scale bar = 1 μm. The gap between the terminal and the postcapillary venule with endothelial fenestration is <1 μm. F, process of fibrocyte; P, pericyte. (From Andres, K. H. *et al.*, 1987, with permission.)

5.03.3.4 Visceral Organs

5.03.3.4.1 Visceral pain

The mechanisms of visceral pain are still poorly understood. Apparently, some inner organs are equipped with specific nociceptors (HTM and polymodal ones; Jänig W. (1996), for review), but their existence has not been proven for all viscera. It is conceivable that the pain from some viscera is mediated not by specific nociceptors but is encoded in the pattern of discharge in populations of relatively unspecific visceral afferents. The clinical observation that a small cut into the gut is not painful, but spasm or ischemia of a larger area causes strong

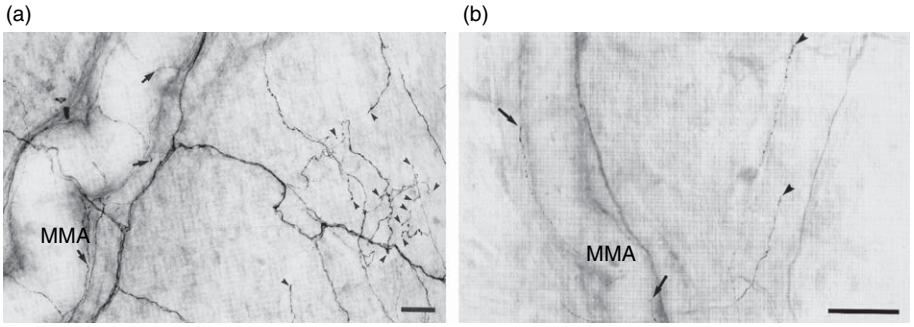

Figure 27 Neuropeptide-ir nerve fibers in the dura mater of the rat. (a) CGRP-ir fibers accompany and cross the middle meningeal artery (MMA). Small bundles of fibers branch off the main bundle and terminate in the connective tissue thereby forming tree-like endings (arrowheads). Some fibers end at the artery (arrows). (b) SP-ir fibers accompanying the MMA. Single beaded nerve fibers terminate at the vessel wall (arrows) or in the connective tissue between blood vessels (arrowheads). (From Hanesch, U., 1996, with permission.)

pain, is generally attributed to the low innervation density of the inner organs.

5.03.3.4.2 Testis

Electrophysiological studies by Kumazawa and coworkers (Kumazawa, T. and Mizumura, K., 1980; Kumazawa, T. *et al*., 1987) have shown that in the tissue layers covering the seminiferous tubules in the rat, endings with unmyelinated afferent fibers are present that behave like polymodal nociceptors in that they can be activated by mechanical stimuli, pain-producing substances, and heat. The innervation density of the tissue is low, and the receptive endings are located directly underneath the tunica albuginea. These properties made it possible to relate the mechanosensitive spots found in electrophysiological experiments to structures in histological specimen.

Kruger L. and coworkers (2003b) used this approach to elucidate the ultrastructure of nociceptive endings of the testis. In the electrophysiological experiments, the location of the receptive ending was marked with insect pins. The endings were reconstructed from serial electron microscopic sections (Figure 28), and in general they showed the features described above for putative nociceptors in other tissues. The preterminal axon had expansions (varicosities) with axonal constrictions in between. Approaching the terminal proper, the axons often lost their microtubules and neurofilaments. Instead, a network of axonal reticulum (probably endoplasmic reticulum) appeared that was embedded in a granular matrix (similar to the receptor matrix of Andres, K. H. and von Düring, M., 1973). This arrangement of an axonal reticulum in a granular matrix (Figure 29) has not been described by other authors, but it is unclear if this arrangement is special for testicular nociceptors, or if it had been overlooked in other tissues.

In the distal tip of the axon, the axolemma exhibited a greater number of exposed areas that directly contacted the basal lamina. The authors stress the presence of clusters of small spherical vesicles, aggregates of mitochondria, and axonal reticulum in a granular matrix in this part of the axon that apparently forms the receptive terminal (Figure 30). Interspersed between the spherical vesicles were so-called granular vesicles that differed somewhat from the dense-core vesicles of endings containing catecholamines and, therefore, could be distinguished from sympathetic nerve endings.

The functional interpretation of the ultrastructure of the terminal poses some problems: Even though it is characterized by special features (vesicle clusters, mitochondria, and exposed axolemma), the axonal zones close to the terminal likewise exhibited some of these specializations. Therefore, it is difficult to decide if only the ultimate terminal is the receptive site where the electrical receptor potential originates or if also other parts of the preterminal branches can be viewed as receptive, as in the sensory tree concept. An important question in this context is where the generator portion of the nociceptor axon is located and if it exhibits structural specializations different from those of the receptive terminal.

5.03.4 Neuropeptide Content of Nociceptors

5.03.4.1 General Remarks

In many cells, neurotransmitters coexist with neuropeptides, or one neuron contains more than

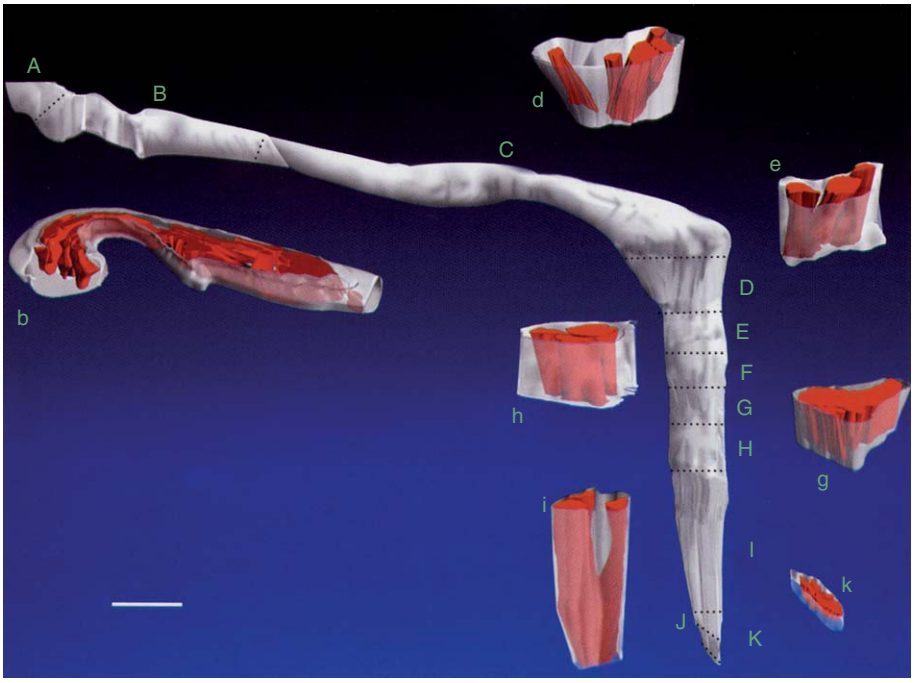

Figure 28 Three-dimensional reconstruction of a pin-marked receptive field (RF) identified from a physiologically characterized nociceptor polymodal fiber discharge in an *in vitro* canine testicular preparation based on a series of semithin (~1 μm) sections from which ultrathin sections were obtained in each of the sectors, labeled A–K. In the segments indicated in lower case, axons are shown in red and Schwann cell basal lamina boundaries in white. Scale bar = 1 μm. (From Kruger, L. *et al.*, 2003b, with permission.)

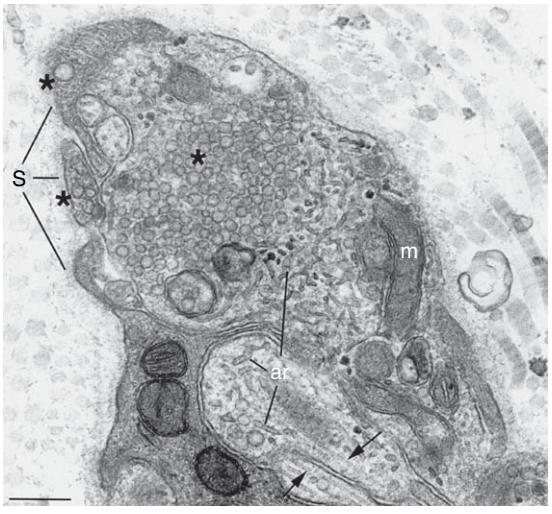

Figure 29 Electron micrograph (from sector E of Figure 28) displaying a putative receptive terminal containing a characteristic preterminal array of axonal reticulum (ar), microtubules (arrows), glycogen granules, and spherical vesicles (asterisks) embedded in a granular matrix and clustered below a surface ensheathed by dark Schwann cell processes (S) and containing vesicles. The bare upper axolemma is in direct contact with the basal lamina. Scale bar = 0.5 μm. (From Kruger, L. *et al.*, 2003, with permission.)

one neuropeptide. It is well known that a large proportion of SP-expressing DRG neurons also contain glutamate. Another example is that almost all DRG cells that are ir for CGRP also exhibit IR for SP and other neuropeptides (Ju, G. *et al.*, 1987). It is generally assumed that glutamate acts as the main neurotransmitter in nociceptive afferents, whereas the neuropeptides function as neuromodulators that – with few exceptions – enhance the central nervous effects of peripheral noxious stimuli (Hökfelt, T. *et al.*, 1980; Kow, L.-M. and Pfaff, D. W., 1988). The peptides are synthesized in the somata of the DRG or in ganglion cells of cranial nerves. They are transported to both the central and the peripheral terminal of the primary afferent unit.

5.03.4.2 Neuropeptides in Afferent Units of Different Tissues

No neuropeptide has been found that can be considered specific for afferent fibers from a particular tissue. DRG cells projecting in a cutaneous nerve

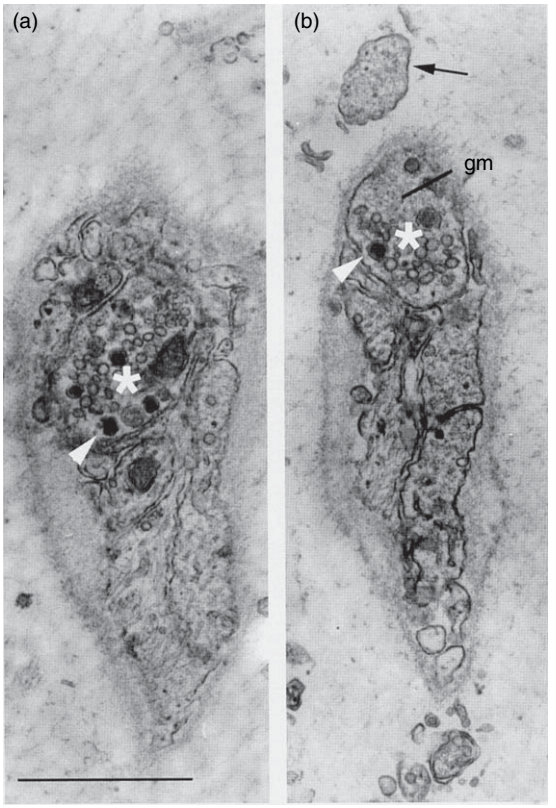

Figure 30 Electron micrograph of the final traced portion of the marked receptive field (RF) indicated in sector K of Figure 28 containing the final vesicle-rich axonal profiles, including several dense-core vesicles (arrowheads), all within a granular matrix (gm) exposed in b to the basal lamina. Arrow, additional unidentified profile. Scale bar = 1 μm. (From Kruger, L. *et al.*, 2003b, with permission.)

have been shown to contain SP, CGRP, and SOM and thus present a peptide pattern similar to that of muscle nerves, whereas visceral afferent units lack IR to SOM (Molander, C. *et al.*, 1987; O'Brien, C. *et al.*, 1989). In comparison to skin nerves, muscle nerves have been reported to contain less SP. This finding has been teleologically explained by assuming that the vasodilatation and plasma extravasation caused by the release of SP and CGRP from afferent fibers would be deleterious for skeletal muscle, since it is surrounded by a tight fascia. Because of the fascia, an SP-induced muscle edema would result in a high increase in interstitial pressure and could cause muscle necrosis. On the other hand, there can be no doubt that a considerable proportion of free nerve endings in muscle exhibit IR to SP and CGRP (Reinert, A. *et al.*, 1998). Therefore, SP and CGRP are likely to be involved in painful alterations of muscle tissue.

5.03.4.3 Neuropeptides in Nociceptors and Other Types of Free Nerve Ending

Whether or not a particular neuropeptide or combination of neuropeptides is associated with a particular type of receptor is obscure. There is evidence from studies on DRG cells (Lawson, S. N. *et al.*, 1997; Djouhri, L. and Lawson, S. N., 2004) indicating that SP-like IR (SP-LI) – and to a lesser extent, also CGRP-LI – was present predominantly in nociceptive units. Arguments supporting a nociceptive function of SP are that noxious stimulation is followed by a release of SP in the dorsal horn, and that the mRNA for SP and other tachykinins is upregulated under these circumstances. On the other hand, there is also evidence speaking against such a relation between the nociceptive function and the presence of SP. In a study by Leah J. D. *et al.* (1985), the great majority (10 out of 12) of individually identified nociceptive DRG cells of the cat did not exhibit SP-LI. Virtually all primary afferent units with SP-LI also exhibited CGRP-LI (Garry, M. G. *et al.*, 1989); both peptides are presumably released together when the fiber is active. In the spinal cord, CGRP has been reported to prolong the action of SP by inhibiting its degradation and to facilitate synaptic transmission in general by enhancing the calcium influx into afferent fibers.

Data from experiments in which single DRG cells with receptive endings in muscle were first functionally identified and then injected with a dye, showed that at least some cell bodies whose peripheral processes terminated in muscle HTM (presumably nociceptive) receptors exhibited CGRP-LI (Hoheisel, U. *et al.*, 1994). However, IR to SP, CGRP, and other neuropeptides was not only present in nociceptive units but also in other types of muscle receptors (e.g., in some muscle spindles and other LTM units). For instance, SP-LI has been found in LTM receptors, e.g., in nerve fibers from Krause corpuscles in the dog's tongue. Most of the cutaneous and deep receptor types studied so far showed CGRP-LI in some of their cell bodies in the DRG (Hoheisel, U. and Mense, S., 1987). The only condition for the presence of CGRP-LI seemed to be that the afferent unit had a small soma size and/or a slow CV.

5.03.5 Efferent Function of Nociceptors

5.03.5.1 Release of Neuropeptides from the Nociceptive Ending

Neuropeptides (e.g., SP, CGRP, VIP, and SOM) are stored in vesicles in the varicosities of the peripheral terminal. Whenever a nociceptor is excited, it releases neuropeptides into the interstitial tissue. SP then releases histamine from mast cells, and together with CGRP these agents cause vasodilatation and an increase in vascular permeability of the blood vessels around the active ending. The result is a shift of blood plasma from the intravascular to the interstitial space. Outside the blood vessel, BK is cleaved from the plasma protein kallidin, and serotonin (5-HT) is set free from platelets and PGs (particularly PG E2) from endothelial and other tissue cells. All these substances sensitize nociceptors. Thus, the main tissue alteration induced by a nondestructive noxious mechanical stimulus is a localized region of vasodilatation, edema, and sensitized nociceptors.

5.03.5.2 The Axon Reflex

The release of neuropeptides from an activated nociceptor is an essential aspect of its function. A nociceptor is not a passive sensor for tissue-threatening stimuli; it actively influences the microcirculation and chemical composition of the interstitial space around it. The morphological basis of the axon reflex is that the branches of a single nociceptive ending can extend over a relatively large area (several hundred micrometers). If a noxious stimulus activates only parts of the ending, the action potentials originating in the regenerative region of the ending can invade antidromically (against the normal direction of propagation) those branches of the ending that were not excited by the stimulus. These antidromic action potentials release neuropeptides from the unstimulated branches. The whole process is called axon reflex. It is assumed to be the reason for the wheal and flare around a cutaneous lesion. The vascular permeability is increased mainly by SP (and by the NK-A and -B; Gamse, R. and Saria, A., 1985), whereas CGRP is assumed to act primarily as a vasodilatator. There is evidence showing that CGRP enhances the plasma extravasation induced by SP and NK-A and -B, but reduces the vasodilatory action of SP by desensitizing muscle arterioles to the peptide (Öhlén, A. *et al.*, 1988).

The area of wheal and flare after a localized damage to the skin – for instance around a needle prick – could be an indicator of the extent of the excited nociceptive ending. Of course, this is true only if a single ending is stimulated and if the distance covered by diffusion of the neuropeptides is constant.

The size of the RFs of cutaneous polymodal nociceptors was found to be $<2\ mm^2$ in cat (Bessou, P. and Perl, E. R., 1969) and $6–32\ mm^2$ in rabbit (Kenins, P., 1988). These figures are greater than the reported length of the branches of a nociceptor ending (a few hundred micrometers). The difference may be due to the fact that nociceptors can be excited from a certain distance, particularly when coarse probes are used. For a muscle nociceptor, the size of the RF can be determined only with limitations, particularly if it is located deep within the muscle. The reported sizes of superficially located fields or the projections of deep RFs on the muscle surface range from spotlike to several square centimeters in the gastrocnemius muscle of the cat and dog (Kumazawa, T. and Mizumura, K., 1977; Mense, S. and Meyer, H., 1985).

5.03.5.3 Neurogenic Inflammation

The release of SP, CGRP, NK-A, and other agents from nociceptors is the central factor in the cascade of events that lead to neurogenic inflammation in the periphery (Lembeck, F. and Holzer, P., 1979). Neurogenic inflammation is characterized by tissue edema and infiltration by immune cells after antidromic activation of nociceptive nerve endings, i.e., when action potentials are generated somewhere along the course of primary afferent units (spinal nerve or dorsal root). The action potentials propagate to both the CNS (causing pain) and the peripheral ending (causing release of neuropeptides and neurogenic inflammation). The published data indicate that vasodilatation can be elicited by antidromic stimulation of both Aδ- and C-fibers, but increase in vascular permeability and plasma extravasation by stimulation of C-fibers only. Neuropathies and radiculopathies and other pathological conditions that are associated with antidromic activity in sensory nerve fibers are examples of such events. Neurogenic inflammation is likely to increase the dysesthesias and pain of patients suffering from neuropathies.

Neuropeptides also influence immune cells (for a review, see Morley, J. E. *et al.*, 1987) and synoviocytes. These actions may be of particular importance for the

development and maintenance of chronic arthritis and other inflammatory disorders of deep somatic tissues.

5.03.6 Receptor Molecules in the Membrane of Nociceptors

Classic stimulants for nociceptors are endogenous pain-producing (algesic) substances such as BK, 5-HT, and high concentrations of potassium ions. Injections of hypertonic NaCl solutions (4.5–6.0%) have been used for many decades to elicit pain from deep somatic tissues. Similar to potassium, the stimulating effects of hypertonic NaCl are considered to be unspecific (i.e., not mediated by a receptor–ligand interaction).

The effects of BK on nerve endings are mediated by G protein-coupled B1 and B2 receptors. Binding of the ligands to this and other receptors of this type results in changes of the state of activation of intracellular second messenger systems such as phospholipase C (PLC), cyclic adenosine monophosphate (cAMP), cyclic guanosin monophosphate (cGMP), and protein kinases (PK). One possible sequel of the activation of these messengers is the phosphorylation of ion channels. This increases the opening time or opening probability of the channels. Collectively, the processes lead either to direct excitation of the ending or to a changed reaction of the nerve ending to external stimuli (sensitization or desensitization).

In intact tissue, the discharges evoked in nerve endings by BK are mainly due to the activation of the BK receptor B2, whereas under pathological conditions the receptor B1 is the predominant one (for a review of receptor molecules mediating the effects of pain-producing substances, see Kumazawa, T., 1996). It is often overlooked that the above substances, particularly BK, excite not only nociceptors but also nonnociceptive endings with thin myelinated and unmyelinated afferent fibers. Therefore, BK cannot be considered a specific excitant of nociceptors. However, muscle receptors with group I and II afferents (e.g., muscle spindles and tendon organs) are not excited by BK.

The stimulating effects of serotonin on nociceptive terminals in the body periphery are largely mediated by the 5-HT3 receptor. Similar to PGE2, which binds to a G protein-coupled prostanoid receptor (EP2), serotonin sensitizes nociceptors rather than exciting them under (patho)physiological circumstances. The reason is that in damaged tissue concentrations of 5-HT and PGE2 are released, which are sufficient for sensitizing, but not for activating, nociceptors.

Novel stimulants for nociceptors are ATP, capsaicin, low pH, and NGF (Caterina, M. J. and David, J., 1999). ATP binds to purinergic receptors (in nociceptive endings, the P2X3 receptor; Ding, Y. *et al.*, 2000) and opens a cation channel. Animal experiments have shown that nociceptors respond to ATP in concentrations that are present in tissue cells. This means that every time a cell is damaged (by trauma or a pathological process), it releases ATP in amounts that can cause pain. For this reason, ATP has been considered a general signal substance for tissue trauma (Cook, S. P. and McCleskey, E. W., 2002).

Capsaicin, the active ingredient of chilli peppers, is a natural stimulant for the vanilloid receptor VR1, now called TRPV1 (Caterina, M. J. and Julius, D., 2001). The receptor is also sensitive to an increase in H^+ concentration and to heat with a threshold of approximately 39 °C. The sensitivity of this receptor to protons is important under conditions in which the pH of the tissue is lowered (exhaustive muscle work, ischemia, and inflammation). TRPV2 is present mainly in myelinated heat nociceptors that have a thermal threshold above 52 °C, and TRPV4 is being discussed as the main receptor of mechano-nociceptors (Liedtke, W., 2005).

A special feature of nociceptive afferent fibers are TTX-r sodium channels. TTX is a neurotoxin that blocks TTX-sensitive sodium channel and thus inhibits conduction in nerve fibers that possess this type of Na^+ channel (mostly large-diameter fibers). Nociceptive fibers are equipped with TTX-r channels; therefore, TTX has no blocking action. Two TTX-r Na^+ channels that are important for nociception are the voltage-gated sodium channels (Na_v) 1.9 and 1.8. Na_v 1.9 has been found exclusively in nociceptive primary afferent neurons, whereas Na_v 1.8 is present in both nociceptive and nonnociceptive ones (for review, Djouhri, L. and Lawson, S. N., 2004).

Glossary

action potential A characteristic pattern of neuronal depolarization and hyperpolarization that mediates transmission of information along the length of the neuron and triggers communication with synaptically connected neurons.

afterpotential The change in membrane potential that follows the action potential.

cable properties Passive electrophysiological properties of a neuron that influence the movement of charge, and therefore the spread of a change in

membrane potential, along a neuron. These properties include internal resistance (influenced by the diameter of the neural process), membrane resistance (influenced by the number of open ion channels in the membrane), and membrane capacitance (determined by the total membrane surface area).

generator potential Membrane depolarization resulting from the transduction of environmental stimuli (i.e., thermal, mechanical, or chemical). This transduction results in a change in membrane conductance that underlies the change in membrane potential.

G-protein-coupled receptors A diverse family of membrane proteins that trigger changes in cell function by signaling through intracellular guanine nucleotide-binding proteins.

hyperalgesia A state in which the sensitivity of nociceptive signaling pathways to environmental stimuli is enhanced.

inflammatory pain Spontaneous pain or hypersensitivity to environmental stimuli arising from inflammation in areas innervated by nociceptive neurons.

length constant A measure of the distance over which a current injected at a point source will spread within a neuron.

neurotrophins A diverse family of soluble signaling molecules that promote the differentiation, survival, and/or function of neurons.

nociceptor Specialized sensory neuron whose activation signals the presence of noxious, or potentially damaging stimuli. These neurons are selectively activated by noxious stimuli, under normal circumstances, or by molecules released once tissue damage has already occurred.

neuropathic pain Spontaneous pain or hypersensitivity to environmental stimuli arising from damage to neural tissue.

receptive field The area in or on the body within which adequate stimuli are capable of generating activity in a given neuron.

polymodality The ability of a molecule or neuron to be activated by more than one type (modality) of stimulus (e.g., mechanical and chemical).

tranduction A process in which environmental stimuli evoke conformational changes in the structure of specific proteins located on nociceptor terminals that directly or indirectly (i.e., via cellular signaling cascades) trigger the opening or closing of ion channels.

transient receptor potential A historically based name for a family of related iron channels that are prevalent in nociceptive neurons and other sensory neuron subtypes.

5.04.1 Introduction

The perception of pain is usually triggered when mechanical, chemical, or thermal stimuli of high intensity or a particular quality are detected by a specialized subpopulation of sensory neurons referred to as nociceptors. Although the term nociceptor has probably outlived its utility, we will use it here as a means of distinguishing afferents capable of responding to tissue damage from those that normally only encode innocuous stimuli. Nociceptor activation typically begins with transduction, a process in which environmental stimuli evoke conformational changes in the structure of specific proteins located on nociceptor terminals that directly or indirectly (i.e., via cellular signaling cascades) trigger the opening or closing of ion channels. The resulting changes in ionic flow across the plasma membrane produce a change in membrane potential, referred to as a generator potential. If the generator potential reaches a critical threshold, action potential firing ensues. In order for these action potentials to trigger a perception of pain, however, they must be propagated to the central terminal of the sensory neuron and subsequently evoke neurotransmitter release in sufficient quantities to activate postsynaptic spinal cord neurons. Thus, there are multiple critical steps in the afferent transmission of nociceptive information, each of which involves a unique compilation of specialized proteins. We will begin this chapter by describing several important but sometimes overlooked anatomical and physiological features of nociceptive neurons. We will then introduce some of the major protein classes that contribute to transduction and, to a more limited extent, the ensuing neurophysiological processes that result in the transmission of nociceptive information to the spinal cord. Subsequently, we will provide a glimpse at how such variables as molecular heterogeneity,

intermolecular interactions, posttranslational modifications, and ion channel distribution can vastly expand the sensory versatility of the nociceptive neurons. Finally, we will describe in greater detail a few of the changes that underlie nociceptor signaling plasticity in the context of inflammation and nerve injury. Although neurotransmission within the spinal cord dorsal horn represents another important function of nociceptors, we will defer a description of this process to other chapters of this volume.

5.04.1.1 Structure Dictates Function: The Anatomy of the Nociceptor

Sensory neurons are referred to as pseudounipolar neurons because they start out during development as bipolar neurons with a central process extending into the spinal or trigeminal dorsal horn and a peripheral process extending out to peripheral targets. During development, the initial segment of these two processes merges to form a T junction, leaving the cell body attached to peripheral and central processes via a single short length of axon (Fitzgerald, M., 2005) (Figure 1). Both central and peripheral processes terminate in a branching pattern referred to as a terminal arbor (Figure 1). The extent of the peripheral arbor depends on the afferent type and site of innervation. For example, afferents innervating the fingertips may innervate a square millimeter or less of skin, and therefore appear to have relatively few terminal branches (Darian-Smith, I. *et al.*, 1980; Andrew, D. and Greenspan, J. D., 1999). In contrast, afferents innervating a visceral structure such as the colon may have an extensive terminal arborization that extends over many centimeters of tissue (Berthoud, H. R. *et al.*, 2004). Afferents responsible for the transduction of low-threshold mechanical stimuli such as brush or vibration terminate in specialized structures such as Rufinni endings or Merkel discs that are critical for mediating the appropriate response to these stimuli (Mearow, K. M. and

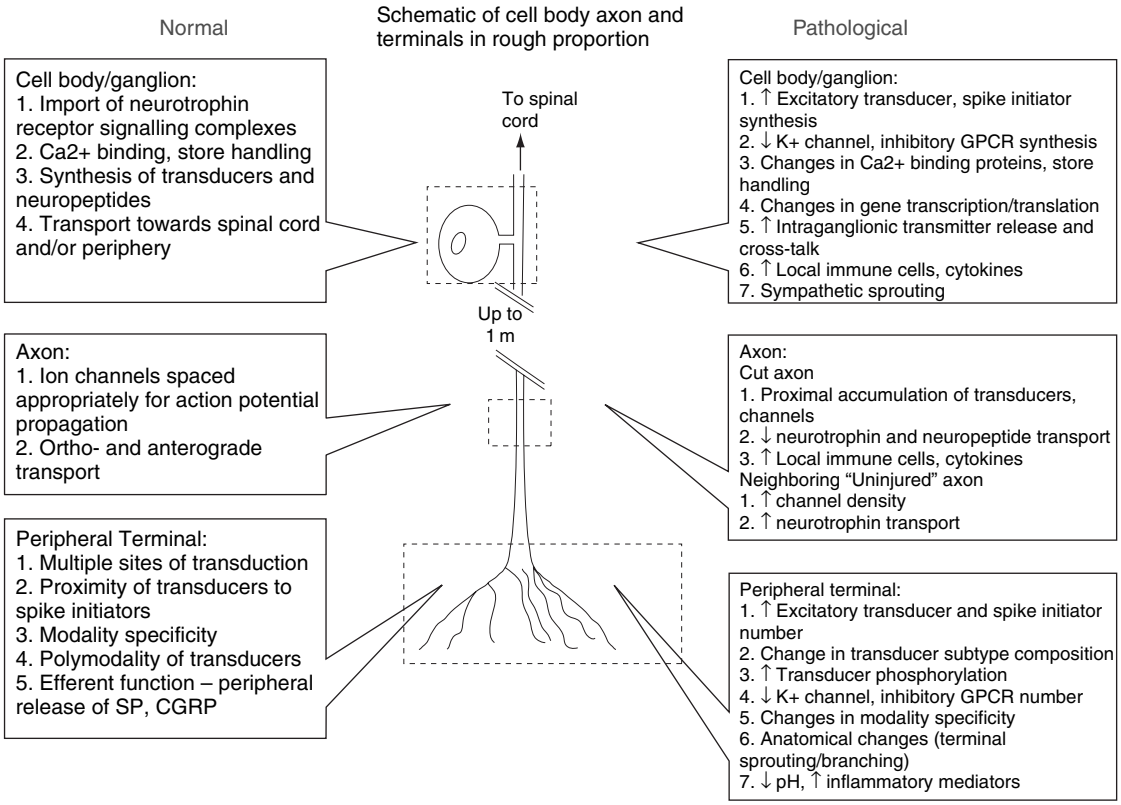

Figure 1 Schematic diagram of three major peripheral compactments of a nociceptive neuron: the cell body (top), axon (middle), and peripheral terminal arbor (bottom). Blowups at left: functional and anatomical properties of these compartments under normal conditions. Blowups at right: characteristic changes associated with nerve injury or inflammation.

Diamond, J., 1988; Johnson, K. O., 2001). In contrast, nociceptors are said to have free nerve endings, because peripheral terminals of these afferents do not appear to be associated with any specific cell type (Kruger, L. *et al*., 2003a). Further description of this anatomical arrangment can be found in the chapter by Mense in this volume (Chapter Anatomy of Nociceptors).

There are at least three important implications of the observation that peripheral terminals of nociceptors are free. First, while recent evidence suggests that transduction may occur in cells surrounding nociceptive terminals (i.e., urothelial cells (Birder, L. A., 2005) or keratinocytes (Guler, A. D. *et al*., 2002; Peier, A. M. *et al*., 2002b; Khodorova, A. *et al*., 2003; Wu, G. *et al*., 2004a) (see below)), the fact that nociceptive terminals are generally not associated with specialized cells suggests that these neurons themselves possess the machinery necessary for transduction. Consistent with this suggestion, the isolated cell bodies of putative nociceptors *in vitro* have been show to respond to thermal (Cesare, P. and McNaughton, P., 1996; Reichling, D. B. and Levine, J. D., 1997; Reid, G. and Flonta, M., 2001; Thut, P. D. *et al*., 2003), mechanical (McCarter, G. C. *et al*., 1999), and various chemical (Baccaglini, P. I. and Hogan, P. G., 1983) stimuli. Second, if transduction machinery is present in nociceptive terminals, transduction may occur whenever and wherever a transducer is properly positioned in the cell membrane. The result is that transduction can and probably does occur at multiple sites in a peripheral arbor (Gover, T. D. *et al*., 2003; Zhao, J. *et al*., 2006). This has important implications for spike initiation and integration of stimuli applied throughout a receptive field (Darian-Smith, I. *et al*., 1980). It also has important implications for the generation of ectopic activity in the presence of injury as there is evidence that the cut ends of axons may rapidly develop mechanical, thermal, and chemical sensitivity (Michaelis, M. *et al*., 1999) and that spontaneous activity may arise from within sensory ganglia following nerve injury (Kajander, K. C. *et al*., 1992). Third, because nerve endings are not only free of an association with a specific cell type, but free of even perineurial encapsulation (Devor, M., 1999), these endings are not only accessible to the chemical milieu of the tissue, but may be accessible to therapeutic interventions.

Both light and electron micrographic analyses of nociceptive terminals reveal complex anatomical structures. As suggested above, the structure of the terminal arbor varies with target of innovation. There is also evidence that subpopulations of nociceptive afferents have distinct terminal arbor patterns within the same structure. For example, the terminal arbor morphology of cutaneous C fibers varies according to whether the C fiber is peptidergic (i.e., expresses substance P or calcitonin gene-related peptide (CGRP)) or expresses the mas-related gene (mrg), MrgD (Zylka, M. J. *et al*., 2005). Furthermore, in the cornea, the terminal arbor of C-fiber afferents is distinct from that of Aδ fibers (MacIver, M. B. and Tanelian, D. L., 1993). At an ultrastructural level, nociceptive terminals appear to have beaded endings with clusters of organelles such as mitochondria at sites of swelling (Kruger, L. *et al*., 2003b). While the functional implications of this beaded structure remain to be determined, it has been suggested that swellings may be sites for transduction and/or the peripheral release of transmitter.

Finally, it is clear that active membrane properties, and therefore the nature of the afferent signal, are influenced by an interaction between the distribution, density, and biophysical properties of ion channels and transducers present in afferent terminals and the morphological features of the terminal arbor. Cable theory describes the impact of leak channels, terminal branch points, and irregularities in membrane shape such as those associated with the beaded pattern described above. As a first pass, all of these features, in addition to the relatively large surface-to-volume ratio associated with fine terminals suggest that the length constant, a measure of the distance over which a current injected at a point source will spread within the terminal, is quite small in nociceptive terminals. This implies that there are likely to be multiple sites of spike initiation throughout the terminal arbor. Importantly, it is likely that the cable properties, and therefore length constant, of nociceptive terminals are dynamically regulated. This notion is based on the observation that potassium leak currents, which determine membrane resistance, may be regulated by a number of factors such as transmitters and second messengers (Maingret, F. *et al*., 2000). Furthermore, evidence from dorsal horn neurons (Mantyh, P. W. *et al*., 1995) suggests that terminal morphology may be rapidly altered. Importantly, a change in a length constant may influence active membrane properties such as action potential threshold and spike accommodation.

5.04.1.2 Nociceptor Inputs and Outputs: More than Meets the Eye

The major focus of this chapter is on molecules involved in the initiation of fast orthograde electrical signaling by nociceptors to the central nervous system. However, several physiological features of nociceptors fall outside this conventional framework but are important within the larger context of sensory transduction. Therefore, before we dissect the mechanisms of nociceptor stimulus transduction, action potential generation, and action potential propagation in any detail, it is worth considering a few of these features.

5.04.1.2.1 The onset of nociceptor excitation: hyperpolarization versus depolarization

Sensory transduction in the mammalian nervous system can arise from either membrane hyper-polarization or membrane depolarization. The visual system utilizes the former while the somatosensory system utilizes the latter. Consequently, in the absence of stimuli, the resting membrane potential of nociceptive afferents is relatively hyperpolarized, with little, if any spontaneous activity (Rose, R. D. *et al.*, 1986; Ritter, A. M. and Mendell, L. M., 1992). This resting membrane potential appears to reflect a relatively large K^+ conductance through both voltage-insensitive (Baumann, T. K. *et al.*, 2004) and voltage-gated K^+ channels (Kirchhoff, C. *et al.*, 1992). However, this K^+ conductance appears to be working against a relatively high membrane permeability to depolarizing cations (i.e., Na^+ and Ca^{2+}), at least in cutaneous afferents (Kirchhoff, C. *et al.*, 1992). Data from studies of the isolated sensory neuron cell body *in vitro* suggest that a significant depolarizing conductance may be present in a relatively large percentage of putative nociceptive afferents (Viana, F. *et al.*, 2002).

There are at least two implications of a significant depolarizing conductance in nociceptive afferents. First, it suggests that a viable mode of transduction may involve the closing of a K^+ channel. In the absence of a depolarizing conductance, closing a K^+ channel in a membrane in which K^+ conductance is the only major conductance responsible for the establishment of the resting membrane potential, will result in little, if any change in membrane potential. Consistent with the suggestion that there is a significant depolarizing conductance in putative nociceptive afferents, there is evidence that some forms of cold transduction reflect the closing of a K^+ channel (Reid, G. and Flonta, M., 2001; Viana, F. *et al.*, 2002). Second, the presence of a significant depolarizing conductance in nociceptive afferents suggests that the resting membrane potential will be relatively depolarized. This has been observed repeatedly in studies on dissociated sensory neurons, where the resting membrane potential of putative nociceptive afferents is more depolarized than that of putative non-nociceptive afferents (see Gold, M. S. *et al.*, 1996a). There is evidence that intact nociceptive terminals *in situ* may be depolarized as well (Brock, J. A. *et al.*, 2001). As mentioned above, resting membrane potential may influence not only transduction, given the voltage dependence of several transducers (see below), but also spike initiation.

5.04.1.2.2 Efferent function

It is clear that nociceptor afferent neurotransmission contributes to the perception of pain associated with tissue injury (Treede, R. D. *et al.*, 1992). However, it is also clear there are tissues distributed throughout the body that are heavily innervated by nociceptive afferents, but that will never give rise to the sensation of pain in many of us. For example, even though pericardial tissue receives nociceptive innervation thought to be responsible for pain associated with cardiac ischemia (Immke, D. C. and McCleskey, E. W., 2001), the majority of us will never experience discomfort arising from this structure. What might be the function(s) of nociceptors in these locations? One potential answer to this question stems from the ability of many nociceptors to release bioactive substances with the potential to exert trophic and/or inflammatory effects on targets of innervation. For example, CGRP, which can be released by many nociceptive neurons, has been shown to regulate cellular activity underlying bone formation and resorption, two processes critical to the maintenance of healthy bone (Lerner, U. H., 2002). Such seemingly paradoxical efferent nociceptor activity is particularly important in tissues subjected to injury. Under these circumstances, the release of transmitters from the peripheral nociceptor terminals has been shown to contribute to local hyperemia and plasma extravasation (hallmarks of the so-called neurogenic inflammation), to the orchestration of tissue repair, and to the initiation and maintenance of pain and hyperalgesia (Willis, W. D., 1999). Much of the focus in this area has been on nociceptor release of CGRP and another peptide transmitter, substance P (Figure 1). However, it is now clear that glutamate is also released into the periphery, where it appears

able to act in an autocrine fashion to further activate and/or sensitize nociceptive afferents (deGroot, J. *et al*., 2000). Appreciation of these efferent capabilities has led to the suggestion that a better name for nociceptive sensory neurons might be noceffector afferents (Kruger, L., 1988).

Three mechanisms have been described that may contribute to the injury-induced efferent release of neurotransmitter. One is the axon reflex, thought to be mediated by action potential spread from one branch in a terminal arbor to other branches (Lewis, T., 1935). A second, relatively rare, mechanism is axonal coupling, in which axons traveling in the same bundle may, as a result of injury, come into such close proximity that activity in one axon is able to initiate activity in a second axon (Meyer, R. A. *et al*., 1985). A third mechanism actually involves the initiation of action potentials in the central terminals of nociceptive afferents within the spinal cord dorsal horn that are propagated antidromically out into the periphery (Sluka, K. A. *et al*., 1995). While the exact mechanism of this activation is still debated, there is evidence that in the presence of inflammation there is a change in presynaptic gamma-aminobutyric acid (GABA) ergic input, such that primary afferent-driven GABA release from interneurons is capable of action potential generation at central terminals (Sluka, K. A. *et al*., 1995). A fourth mechanism, often overlooked in this discussion, involves the possible direct coupling between calcium-permeable transducers and transmitter release. Such a mechanism appears to contribute to the inflammation associated with capsaicin-induced activation of its receptor transient receptor potential vanilloid 1 (TRPV1) (see below).

5.04.1.2.3 Spike integration within the cell body

There is evidence indicating that once the T junction is formed within the sensory ganglia, action potentials need not invade the sensory neuron cell body (Amir, R. and Devor, M., 2003). This observation begs the question of why action potentials invade the cell body at all. One answer to this question appears to be that the invading action potential provides a mechanism for the recruitment of additional activity. The term cross-excitation has been used to describe the observation that activity in one axon can induce activity in neighboring axons (Devor, M. and Wall, P. D., 1990). Interestingly, the prevalence of cross-excitation increases in the presence of tissue injury, providing a mechanism for peripherally mediated secondary hyperalgesia (Devor, M. and Wall, P. D., 1990). While the exact mechanisms underlying such cross talk have yet to be completely worked out (Amir, R. and Devor, M., 1996), there is evidence that the sensory neuron cell body is capable of releasing transmitter (Huang, L. Y. and Neher, E., 1996) and that peripheral nerve stimulation results in the release of transmitter within the ganglia (Matsuka, Y. *et al*., 2001).

More relevant to the issue of transduction, however, is the observation that afferent activity is capable of driving changes in gene transcription (Figure 1). For example, there is evidence that electrical activity in sensory neurons is capable of changing Na^+ channel expression (Klein, J. P. *et al*., 2003). Interestingly, the pattern of activity appears to influence the pattern of gene transcription (Fields, R. D. *et al*., 2005). The result may be as profound as to determine whether or not sprouting axons are able to coalesce into a nerve. One mediator that appears to be critical for the integration of activity within the cell body is Ca^{2+}, acting through a number of Ca^{2+}-dependent molecules (Eshete, F. and Fields, R. D., 2001). Thus, the transduction of activity within the sensory neuron cell body involves the influx of Ca^{2+}, which then initiates a number of cellular processes including gene transcription.

5.04.1.2.4 Slow axonal transport

Another general mechanism critical to nociceptive signaling involves axonal transport to the cell body, rather than action potential propagation. This is a remarkable process, given the tremendous length of sensory nerve axons (up to 1 m), relative to their soma size (~18–30 μm). Among the primary functions of this form of signaling, which may take hours to days, are the maintenance of nociceptor survival during development, the maintenance of nociceptive phenotype and function in the adult, and orchestration of the afferent response to tissue injury (Koltzenburg, M., 1999). The best-studied example of signaling via slow axonal transport is that of neurotrophic factors bound to their receptors (Figure 1) (Zweifel, L. S. *et al*., 2005). However, slow axonal transport can also lead to signaling in the distant sensory neuron cell body following ligand-dependent internalization of G-protein-coupled receptors (GPCRs) (e.g., those for neurokinins, opioids, and extracellular proteases) (Tseng, L. F. and Narita, M., 1995; Vergnolle, N. *et al*., 2001). In addition, transcription factors, second messenger molecules, cell surface glycoproteins, and foreign particles such as plant lectins, toxins, and viruses can all be transported retrogradely from peripheral sensory

neuron terminals toward the cell body (Wang, H. F. *et al.*, 1998; Vulchanova, L. *et al.*, 2001; Tarpley, J. W. *et al.*, 2004; Yeomans, D. C. *et al.*, 2005; Mata, M. *et al.*, 2006). In what has been a boon to researchers, there are some molecules that are selectively taken up by subpopulations of sensory neurons, and have therefore been used to characterize innervation patterns (see Wang, H. F. *et al.*, 1998). Sensory neurons also appear to be able to take up inflammatory mediators such as TNFα (Schafers, M. *et al.*, 2002). Exactly how sensory neurons use the information associated with the presence or absence of various molecules transported back to the cell body remains to be determined. However, the internalization and transport of molecules present at sensory neuron terminals appears to be a mechanism for sensory neurons to monitor tissue integrity and adjust to changes in the local environment.

5.04.2 The Molecular Toolbox of Sensory Neurons

Sensory neurons express a multitude of cell surface proteins that serve anatomically as markers of neuronal subtypes and functionally as mediators of the fundamental signaling and transmission functions outlined in the previous section. Three classes of sensory neuron cell surface proteins have been studied in the greatest detail: ion channels, metabotropic GPCRs, and receptors for neurotrophins or cytokines. Together, these proteins endow sensory afferents with responsiveness to a qualitatively and quantitatively diverse collection of environmental variables and dictate the passive and active properties essential for converting a generator potential into a signal that reaches the spinal cord. As detailed below, certain membrane proteins found in nociceptors (e.g., P2X3, TRPM8, mrgA, and NaV1.8) are expressed within subsets of sensory neurons at levels much higher than anywhere else in the body. Such enriched expression has provided reagents that can be used for sensory neuron- or nociceptor-specific gene disruption or transgene expression in the laboratory setting. More importantly, it provides at least the theoretical opportunity to develop antinociceptive drugs that have minimal effects on other cell types. A few of the more prominent classes of cell surface proteins expressed in sensory neurons are described below.

5.04.2.1 Ion Channels Involved in the Transduction of Extracellular Signals

5.04.2.1.1 P2X adenosine triphosphate-gated ion channels

Extracellular adenosine triphosphate (ATP), released upon cell damage, has been recognized as a nociceptive stimulus ever since the demonstration that application of this molecule to a blister base produces pain in human psychophysical studies (Bleehan, T. and Keele, C. A., 1977). At least one mechanism by which ATP activates nociceptors is via activation of ATP-gated ion channels of the P2X family. These channels are comprised of a heterotrimer of P2X subunits, each with two transmembrane domains and a large extracellular loop that contains the ATP binding site. Seven P2X subtypes have been cloned in mammals. They differ with respect to their sensitivity to ATP or ATP analogs, as well as the kinetics of their ATP-evoked currents. For example, homomeric P2X3 is responsive to α,β-methylene ATP, and exhibits a rapidly desensitizing current response, whereas homomeric P2X2 exhibits slowly desensitizing currents that are α,β-methylene ATP insensitive. When coassembled, these channels form an α,β-methylene sensitive, slowly desensitizing heteromultimeric channel. P2X channels are typically nonselective cation channels that exhibit considerable permeability to both Na^+ and Ca^{2+} ions. In several cases, however, (P2X2, P2X4, and P2X7) protracted stimulation of these channels can lead to an apparent dilation of the channel pore, such that much larger organic cations such as *N*-methyl D-glucamine are able to permeate the channel. The significance of this dynamic ion selectivity remains unclear (North, R. A., 2002).

Although mRNAs encoding P2X1 through P2X6 have all been detected in sensory neurons, P2X2 and P2X3 appear to be expressed most prominently in these cells. P2X2 is expressed in neurons with a wide range of cell body sizes. In contrast, at least in skin, P2X3 expression appears to be confined to a subpopulation of small-diameter sensory neurons that bind isolectin B4 (IB4) and that project to inner lamina II of the spinal cord dorsal horn (North, R. A., 2002). It is important to note, however, that the precise relationship between P2X3 expression and IB4 binding may vary between cutaneous afferents with their cell bodies in dorsal root ganglia and other nociceptor populations such as those in the trigeminal ganglion (Ambalavanar, R. *et al.*, 2005). Genetic disruption of both P2X3 and P2X2 results

in elimination of all transient ATP-evoked currents and all but a small persistent ATP-evoked current in cultured sensory neurons (Cockayne, D. A. *et al.*, 2005).

P2X channels also contribute to pain sensation *in vivo*. For example, although application of P2X3 antagonists (Jarvis, M. F. *et al.*, 2002; McGaraughty, S. *et al.*, 2003) or antisense oligodeoxynucleotide-mediated knockdown of P2X3 (Barclay, J. *et al.*, 2002; Honore, P. *et al.*, 2002) have no apparent effect on acute nociceptive responses to mechanical or thermal stimuli, both interventions have been shown to reduce thermal and/or mechanical hyperalgesia associated with complete Freund's adjuvant (CFA) administration into the paw and several models of neuropathic pain, as well as reducing the extent of the first and second phases of paw licking following intraplantar formalin injection. Gene knockout of P2X3 or P2X2/3 receptors in mice has also been reported to diminish formalin-evoked nocifensive behavior. However, these knockout animals exhibit a perplexing mixture of pain-related phenotypes, including paradoxically enhanced behavioral avoidance of heat and cold stimuli (Cockayne, D. A. *et al.*, 2000; Souslova, V. *et al.*, 2000; Cockayne, D. A. *et al.*, 2005; Shimizu, I. *et al.*, 2005). In visceral structures, epithelial cells appear capable of the storage and Ca^{2+}-dependent release of ATP in response to mechanical and chemical stimuli. P2X3 and P2X2/3 receptors on primary afferent terminals enable visceral afferents to respond to this released ATP, perhaps contributing to visceral pain sensation (Cockayne, D. A. *et al.*, 2000; Vlaskovska, M. *et al.*, 2001; Andersson, K. E., 2002; Birder, L. A., 2005). A similar mechanism may underlie ATP-mediated stimulus transduction in cutaneous tissue in the presence of inflammation (Wu, G. *et al.*, 2004a). P2X receptors contribute to nociceptive neurotransmission in a number of other ways, as well. In the spinal cord, for example, activation of presynaptic P2X3-containing channels and postsynaptic P2X channels of other subtypes, modulates neurotransmitter release and excitability, respectively (Gu, J. G. and MacDermott, A. B., 1997; Nakatsuka, T. and Gu, J. G., 2001; Nakatsuka, T. *et al.*, 2003; Tsuzuki, K. *et al.*, 2003). In addition, although it appears not to be expressed within neurons themselves, P2X7 is necessary for normal inflammation, nerve injury-induced hyperalgesia (Chessell, I. P. *et al.*, 2005), and CFA-induced hyperalgesia in rats (Dell'Antonio, G. *et al.*, 2002a; 2002b), probably owing to its role in cytokine release from inflammatory cells (Labasi, J. M. *et al.*, 2002).

5.04.2.1.2 Proton-gated ion channels

Reductions in tissue pH, as might occur during ischemia or inflammation, can potently activate nociceptors and sensitize them to heat and other stimuli. *In vitro*, low pH activates cationic channels in sensory neurons that can exhibit transient, sustained, or biphasic kinetics (Bevan, S. and Yeats, J., 1991). At least some of these responses can be attributed to the acid-sensing ion channel (ASIC) family. These multimeric ion channels are comprised of subunits that topologically resemble the P2X channels, with two transmembrane domains each and an extracellular ligand (H^+) binding domain. Five ASIC subtypes have been cloned, of which four (ASIC1–4) are expressed in peripheral sensory neurons (Waldmann, R. *et al.*, 1999; Waldmann, R., 2001). Splice variants of several subtypes add to the overall complexity, and one such variant, ASIC1β, appears to be selectively enriched in sensory neurons (Chen, C. C. *et al.*, 1998). Upon activation by low pH (from <7 to <4, depending on the subtype) ASICs typically mediate a prominent and rapidly desensitizing Na^+ current. However, some subtypes (e.g., ASIC3), exhibit a biphasic current consisting of an initial desensitizing sodium current, followed by a more sustained current that includes Ca^{2+} ions (Waldmann, R. *et al.*, 1999; Waldmann, R., 2001).

Several lines of evidence support the participation of ASIC channels in acid responsiveness of sensory neurons. First, the kinetics of sensory neuron responses to a pH 6 stimulus are altered in neurons isolated from ASIC1, ASIC2, or ASIC3 knockout mice or in wild-type neurons exposed to APETx2, an ASIC3-selective antagonist from sea anemone (Price, M. P. *et al.*, 2001; Benson, C. J. *et al.*, 2002; Xie, J. *et al.*, 2002; Diochot, S. *et al.*, 2004). Second, pH 5-evoked C-fiber responses are reduced in *ex vivo* skin–nerve explants derived from ASIC3 knockout mice (Price, M. P. *et al.*, 2001). Third, mice lacking ASIC3 exhibit defects in the ipsilateral mechanical hyperalgesia that typically develops 4 h after injection of acid to the gastrocnemius muscle (Price, M. P. *et al.*, 2001) as well as defects in the bilateral hyperalgesia that develops after two intramuscular acid injections, 5 days apart (Sluka, K. A. *et al.*, 2003). Interestingly, no changes in behavioral responses to acute subcutaneous acid injection have been reported in these knockout studies. However, ASIC3 may be particularly important for sensing reductions in muscle pH during ischemia (Immke and McCleskey 2001).

In addition to acid detection, ASICs have also been implicated in mechanosensation. This

hypothesis was initially based upon the recognition that ASICs bear structural and pharmacological similarities (i.e., amiloride sensitivity) to degenerins, cationic channels identified in genetic screens for mechanosensory defects in the nematode, *Cenorhabditis elegans* (O'Hagan, R. and Chalfie, M., 2005). The immunolocalization of ASIC2 and 3 to sensory afferent terminals (Price, M. P. *et al.*, 2000; Garcia-Anoveros, J. *et al.*, 2001; Price, M. P. *et al.*, 2001) and the systematic examination of mechanosensation in ASIC knockout mice have lent support to this notion. Mice lacking ASIC1 were recently reported to exhibit no detectable changes in mechanoreceptor properties in the skin–nerve preparation. However, there was an enhancement of mechanically evoked firing rate in gastrointestinal afferents in these mice, accompanied by a reduction in gastric emptying rate (Page, A. J. *et al.*, 2004). Studies of ASIC2 KO mice have yielded somewhat conflicting results. In one study, these mice were reported to exhibit reduced mechanically evoked firing rate of rapidly adapting Aβ mechanoreceptors (RAM), without a change in RAM threshold (Price, M. P. *et al.*, 2000). In another study, however, no change in RAM response characteristics was observed (Roza, C. *et al.*, 2004). ASIC3 KO mice were reported to exhibit decreased sensitivity of Aδ mechanoreceptors but increased sensitivity of RAM, together with increased behavioral withdrawal from mechanical stimulation after carageenan (Price, M. P. *et al.*, 2001).

In contrast to the situation for acid detection, it has been relatively difficult to correlate mechanically evoked currents with the presence of particular ASIC subunits. Indeed a recent *in vitro* study of mechanically evoked currents revealed no differences between wild type and ASIC2 knockout, ASIC3 knockout, or ASIC2/3 double knockout mice. Instead, the authors of this study observed that the cationic dye, ruthenium red, could inhibit mechanosensitive currents, suggesting the possible participation of transient receptor potential (TRP) channels (see below) (Drew, L. J. *et al.*, 2004).

5.04.2.1.3 Transient receptor potential ion channels

One early clue that nociceptive neurons might express signaling proteins distinct from those of other neuronal subtypes was the observation that exposure of neonatal rats to capsaicin, the main pungent ingredient in hot peppers, produces a lifelong depletion of small-diameter sensory neurons, with no such effects on larger-diameter neurons. As adults, these animals exhibit diminished responsiveness not only to subsequent capsaicin challenge, but also to other painful stimuli (Jancso, G. *et al.*, 1977). The highly enriched expression of a vanilloid receptor in nociceptive neurons appears to underlie these incredibly selective effects of capsaicin and related vanilloid compounds (Szallasi, A. and Blumberg, P. M., 1999). This conclusion was corroborated by the molecular cloning of a capsaicin-gated ion channel named TRPV1 (Caterina, M. J. *et al.*, 1997).

TRPV1 belongs to the TRP family, which in mammals contains approximately 30 members. TRP channel subunits have six transmembrane domains and intracellular N- and C-termini, and apparently form tetrameric channels on the cell surface. A remarkable feature of TRPV1 is that, in addition to vanilloid compounds, it can be activated by a number of other stimuli, including protons (pH < 5) (Tominaga, M. *et al.*, 1998), certain endogenous arachidonic acid derivatives (anandamide, *N*-arachidonyl dopamine, and 12-HPETE) (Zygmunt, P. M. *et al.*, 1999; Hwang, S. W. *et al.*, 2000; Huang, S. M. *et al.*, 2002) and even noxious heat (>42 °C) (Caterina, M. J. *et al.*, 1997). Nonvanilloid exogenous chemicals capable of activating TRPV1 include ethanol (Trevisani, M. *et al.*, 2002), camphor (Xu, H. *et al.*, 2005), and 2-aminoethoxydiphenyl borate (2-APB) (Hu, H. Z. *et al.*, 2004).

Sensory neurons derived from TRPV1 knockout mice not only are devoid of vanilloid responsiveness but also exhibit deficits in current responses evoked by pH 5 or moderate heat (45–50 °C) stimuli. All *in vivo* vanilloid-evoked responses are correspondingly absent in TRPV1 knockout mice. These animals also exhibit modestly reduced (but not absent) behavioral responses to acute noxious heat. A far more striking nociceptive phenotype is apparent in these mice following cutaneous inflammation by mustard oil, carageenan, or complete Freund's adjuvant or following surgical incision of the skin. Under these conditions, almost none of the thermal hyperalgesia typically exhibited by wild-type mice is observed in mice lacking TRPV1, although mechanical hyperalgesia is unaffected (Caterina, M. J. *et al.*, 2000; Davis, J. B. *et al.*, 2000; Pogatzki-Zahn, E. M. *et al.*, 2005). More recent pharmacological studies have further supported a role for TRPV1 in inflammatory thermal hyperalgesia (Pomonis, J. D. *et al.*, 2003; Gavva, N. R. *et al.*, 2004; Honore, P. *et al.*, 2005). However, the degree to which this channel may or may not participate in neuropathic pain states is much less clear. Although some pharmacological

studies using TRPV1 antagonists with significant potential for off-target effects have suggested a possible role (Pomonis, J. D. *et al.*, 2003; Walker, K. M. *et al.*, 2003), mice lacking TRPV1 exhibit apparently normal thermal hyperalgesia following partial ligation of the sciatic nerve (Caterina, M. J. *et al.*, 2000). The recent availability of more selective TRPV1 antagonists promises to resolve this issue (Rami, H. K. and Gunthorpe, M. J., 2004). One particularly promising recent finding was that a TRPV1-selective antagonist was shown to partially attenuate the mechanical hyperalgesia associated with experimental bone cancer pain (Ghilardi, J. R. *et al.*, 2005).

Following the identification of TRPV1, a host of other TRP channels were found to be expressed in sensory ganglia. Like TRPV1, many of these channels are polymodal, exhibiting responsiveness to a multiple physical and chemical stimuli (Jordt, S. E. *et al.*, 2003; Patapoutian, A. *et al.*, 2003). Whereas TRPV1 appears to be the only member of this family gated by capsaicin, TRPV2, TRPV3, and TRPV4, like TRPV1, can be activated by elevated ambient temperatures. TRPV2 is expressed most prominently in a subpopulation of neurons with medium- to large-diameter cell bodies. Based on their size, expression of CGRP and neurofilament proteins, and projection pattern within the spinal cord, many of these neurons are likely to correspond to Aδ neurons. However, some presumably Aβ neurons that project within the dorsal columns also appear to express TRPV2. Heterologously expressed TRPV2 can be activated by temperatures >52 °C, a thermal response pattern reminiscent of those exhibited by Type II Aδ fibers in peripheral nerve recording studies and by a subpopulation of medium-diameter, capsaicin-insensitive dorsal root ganglion (DRG) neurons in isolated cultures (Caterina, M. J. *et al.*, 1999). TRPV2 can alternatively be activated by hypo-osmolarity (Iwata, Y. *et al.*, 2003), cell stretch (Muraki, K. *et al.*, 2003), or 2-APB (Hu, H. Z. *et al.*, 2004).

TRPV3 is activated by warm temperatures (>34–37 °C), although its thermal responsiveness extends well into the noxious range (Peier, A. M. *et al.*, 2002b; Smith, G. D. *et al.*, 2002; Xu, H. *et al.*, 2002). This channel can, alternatively, be activated by certain exogenous chemical substances (camphor, 2-APB) (Chung, M. K. *et al.*, 2004b; Hu, H. Z. *et al.*, 2004; Moqrich, A. *et al.*, 2005). The expression pattern of TRPV3 remains somewhat controversial. Although there are reports of TRPV3 mRNA or protein expression in sensory neurons (Smith, G. D. *et al.*, 2002; Xu, H. *et al.*, 2002), its expression in these cells is far less clear than in skin keratinocytes (Peier, A. M. *et al.*, 2002b), where TRPV3-mediated current responses can be readily generated (Chung, M. K. *et al.*, 2004a; Moqrich, A. *et al.*, 2005). These findings have led to the notion that TRPV3 may signal the presence of cutaneous warmth via keratinocyte–sensory neuron communication. Support for a role of TRPV3 in thermosensation has come from the observation that in mice lacking this protein, heat-evoked nociception is blunted in the hot plate and tail immersion assays. In addition, on a thermal gradient, selection of preferred floor temperatures is slowed, but not absent, in these mice (Moqrich, A. *et al.*, 2005).

TRPV4 can be gated by warm temperatures (>32 °C), hypo-osmolarity, cytochrome P450 metabolites of arachidonic acid, or the synthetic phorbol ester, 4α-phorboldibutyryl didecanoate (Nilius, B. *et al.*, 2004). Like TRPV3, TRPV4 is expressed more prominently in keratinocytes than in sensory afferents (Guler, A. D. *et al.*, 2002), although there is evidence for low-level TRPV4 protein expression in a population of medium- to large-diameter sensory afferents (Liedtke, W. and Friedman, J. M., 2003). Mice lacking TRPV4 exhibit reduced sensitivity to noxious mechanical or hypertonic stimuli, prolonged tail immersion latencies at modestly hot temperatures, and a shift in thermal selection behavior toward floor temperatures warmer than those selected by wild-type mice (Liedtke, W. and Friedman, J. M., 2003; Suzuki, M. *et al.*, 2003; Alessandri-Haber, N. *et al.*, 2005; Lee, H. *et al.*, 2005b).

Just as heat can activate TRPV1–TRPV4, cold temperatures have been reported to activate at least two other TRP channels. TRPM8 was identified on the basis of its responsiveness to the cold-mimetic agent, menthol. Examination of its thermosensory responsiveness revealed, however, that it could alternatively be activated by modest reductions in ambient temperature (<22 °C) (McKemy, D. D. *et al.*, 2002; Peier, A. M. *et al.*, 2002a). Another cold-mimetic agent, icilin, can also activate TRPM8, but only when intracellular Ca^{2+} levels are elevated (McKemy, D. D. *et al.*, 2002; Chuang, H. H. *et al.*, 2004). TRPM8 is expressed in a subset of small-diameter neurons that lack expression of TRPV1, substance P or Isolectin B4 (Peier, A. M. *et al.*, 2002a).

Another icilin-sensitive TRP channel that has been implicated in cold sensation is TRPA1. This channel is expressed in a subpopulation of small-diameter sensory neurons and is commonly coexpressed with TRPV1. In some studies, recombinant TRPA1 has been reported to be responsive to intense cooling (<18 °C) (Story, G. M. *et al.*, 2003). Consistent with

this finding, mice lacking TRPA1 were recently reported to exhibit reduced withdrawal behavior on a cold plate or in response to acetone-mediated cooling of the hind paw (Kwan, K. Y. *et al.*, 2006). However, the cold sensitivity of TRPA1 is not universally accepted, since other investigators have failed to detect such responses and have reported normal cold-evoked behavioral responses in a distinct line of TRPA1 null mice (Jordt, S. E. *et al.*, 2004). Another point of contention revolves around the potential contributions of TRPA1 to mechanosensation, which is supported by immunolocalization studies (Nagata, K. *et al.*, 2005) and by analysis of one knockout mouse line (Kwan, K. Y. *et al.*, 2006) but not another (Bautista, D. M. *et al.*, 2006). The basis for these apparent discrepancies remains unclear. However, there is uniform consensus that TRPA1 is a mediator of nociceptive responses to certain irritant chemicals, including mustard oil (allyl isothiocyanate), cinnamaldehyde, and acrolein and that it serves as a downstream target following the activation of bradykinin receptors (Bandell, M. *et al.*, 2004; Jordt, S. E. *et al.*, 2004; Bautista, D. M. *et al.*, 2006; Kwan, K. Y. *et al.*, 2006). Indeed, both lines of TRPA1 null mice were found to be defective in nocifensive behavioral responses to mustard oil injection, mustard oil-evoked allodynia, and bradykinin-evoked pain-like behavior (Bautista, D. M. *et al.*, 2006; Kwan, K. Y. *et al.*, 2006).

Thus far, the examination of TRP channels within sensory neurons has been confined largely to those that either exhibit preferentially high expression in these cells or have been identified as being responsive to chemical stimuli with recognizable sensory effects. However, other TRP channels are known to be expressed quite broadly in neuronal and non-neuronal cells, where they participate in numerous functions that are important to sensory neuron biology (e.g., store-operated Ca^{2+} entry, Mg^{2+} uptake, mechanosensation, axon guidance) (Ramsey, I. S. *et al.*, 2006). Therefore, studies aimed at the analysis of those channels in sensory ganglia may yield further important insights.

5.04.2.2 Ion Channels Influencing Passive Membrane Properties: Membrane Resistance

While a number of channels contribute to the establishment of input resistance, two general classes have been described at a molecular level. One class includes the two-pore K^+ channels. These channels have no intrinsic voltage sensitivity and are active at resting membrane potentials thereby contributing to resting input resistance. TWIK related potassium channel (TREK-1) was the first of these K^+ channels to be identified in sensory neurons. TWIK stands for tandem of P domains in a weak inward rectifier potassium channel (Patel, A. J. and Honore, E., 2001). TREK-1 was cloned in 1996 based on homology to TWIK. While TREK-1 was originally shown to be activated by arachidonic acid and inhibited by cAMP, it was subsequently demonstrated that TREK-1 was activated by membrane stretch, osmotic welling as well as molecules that caused membrane crenation. Two more mechanosensitive two-pore potassium channels, TREK-2 and TRAAK were subsequently described (Maingret, F. *et al.*, 1999; Bang, H. *et al.*, 2000), both of which are also activated by membrane stretch and crenators and both of which are present in sensory ganglia (Kang, D. and Kim, D., 2006). Nevertheless, it remains to be determined whether any of these channels underlies the mechanosensitivity of primary afferent neurons (Patel, A. J. and Honore, E., 2001).

A second class of ion channel that may also contribute to resting input resistance is a member of the voltage-gated Na^+ channel family. One member of this family, NaV1.9 appears to encode a voltage-gated channel with unique gating properties (Cummins, T. R. *et al.*, 1999). The channel has a very low threshold for activation, activates very slowly upon membrane depolarization, and undergoes very little inactivation with small membrane depolarizations. These gating properties have two important consequences. First, it is likely that this channel contributes little, if anything to the rapid upstroke of the action potential. Second, the channel should, in theory, contribute a depolarizing drive at resting membrane potentials (Herzog, R. I. *et al.*, 2001). The problem with this theory is that biophysical analysis of persistent Na^+ currents in sensory neurons (putative NaV1.9-mediated currents) (Priest, B. T. *et al.*, 2005) indicate that this current is subject to a profound slow inactivation (Cummins, T. R. *et al.*, 1999). This voltage and time-dependent process is associated with a channel transition from a closed state, from which it could be activated with membrane depolarization, to an inactivated state, from which the channel is no longer available for activation. The extent of slow inactivation of NaV1.9 is such that there is virtually no detectable persistent current evoked from a typical resting membrane potential (i.e., -60 mV). There is evidence suggesting that the voltage dependence of

slow inactivation is influenced by recording conditions, such that the use of fluoride-based electrode solutions results is a hyperpolarizing shift in the voltage dependence of this process (Coste, B. *et al.*, 2004). Consequently, the extent of inactivation may be overestimated when the whole-cell patch configuration is used, if stability of the internal milieu is as important for the stability of NaV1.9 as it is for other ion channels (Kepplinger, K. J. *et al.*, 2000). Either way, what is clear is that even a few NaV1.9 channels active at rest could have a profound influence on neuronal excitability (Herzog, R. I. *et al.*, 2001).

5.04.2.3 Ion Channels Underlying Active Membrane Processes

5.04.2.3.1 Action potential upstroke

Voltage-gated Na^+ channels are critical for the upstroke, or rapid depolarization, phase of the neuronal action potential. Typical voltage-gated Na^+ channels consist of an α-subunit and two β-subunits (Catterall, W. A., 1992). The α-subunit contains everything necessary for a functional voltage-gated channel, including the ion pore, voltage sensor, and inactivation gate. β-subunits appear to both influence channel gating as well as play a major role in channel trafficking (Isom, L. L., 2001). Recent evidence suggests that one of the β-subunits may also influence channel inactivation (Grieco, T. M. *et al.*, 2005). Nine α-subunits have been cloned and clearly demonstrated to underlie voltage-gated Na^+ currents (Catterall, W. A. *et al.*, 2005a). A tenth α-subunit has been identified that is distantly related to the other nine and has been suggested to function as a Na^+ transporter rather than a voltage-gated channel (Goldin, A. L. *et al.*, 2000). Four β-subunits have been cloned (Goldin, A. L. *et al.*, 2000; Yu, F. H. *et al.*, 2003). There is evidence that eight of the nine α-subunits and all four β-subunits are present in sensory neurons (Black, J. A. *et al.*, 1996; Shah, B. S. *et al.*, 2000; Renganathan, M. *et al.*, 2002; Takahashi, N. *et al.*, 2003). α-subunits are differentially distributed both between and within sensory neurons. For example, NaV1.7, 1.8, and 1.9 are preferentially expressed in putative nociceptive afferents (Fang, X. *et al.*, 2002; Djouhri, L. *et al.*, 2003a; 2003b), while NaV1.1 is preferentially expressed in non-nociceptive afferents (Black, J. A. *et al.*, 1996). Within nociceptive afferents, NaV1.8 appears to be normally localized to the cell body and terminal arbor (Ritter, A. M. and Mendell, L. M., 1992; Jeftinija, S., 1994; Gu, J. G. and MacDermott, A. B., 1997; Brock, J. A. *et al.*, 1998; Khasar, S. G. *et al.*, 1998), while NaV1.6 is present along the axons (Rios, J. C. *et al.*, 2003). Furthermore, there is evidence that channel expression is developmentally regulated. For example, in the rat, expression levels of NaV1.3 and 1.5 are high during development, and then reduced to almost undetectable levels after birth (Waxman, S. G. *et al.*, 1994; Renganathan, M. *et al.*, 2002). Importantly, the pattern of both α- and β-subunit expression is altered both within and between neurons following injury, changes that are thought to play a significant role in pain and hyperalgesia associated with tissue injury.

Voltage-gated Na^+ currents in sensory neurons are generally described in terms of their sensitivity to tetrodotoxin (TTX) where currents are TTX-sensitive (NaV1.1, 1.2, 1.3, 1.6, and 1.7), TTX-insensitive (NaV1.5), or TTX-resistant (NaV1.8 and 1.9). The TTX-resistant currents are further subdivided into inactivating (NaV1.8) and persistent current (NaV1.9). Based on data from biophysical characterization of these subunits and toxin sensitivity, NaV1.8 appears to be largely responsible for spike initiation in the terminals and cell body of nociceptive afferents (Gold, M. S., 2000a), while the TTX-sensitive channels, NaV1.6 and NaV1.7, are likely to underlying action potential conduction. Recent evidence from the NaV1.7 null mutant mouse suggests that NaV1.7 may also play a significant role in action potential generation in nociceptive afferent terminals (Nassar, M. A. *et al.*, 2004). A small cohort of individuals was also recently identified who do not experience pain in response to noxious stimuli, even though they appear to be aware of stimuli that should produce pain, exhibiting few, if any detectable somatosensory abnormalities (Cox, J. J. *et al.*, 2006). All of these individuals possess loss of function mutations in NaV1.7, indicating that this channel is necessary for the stimulus evoked perception of pain.

5.04.2.3.2 Action potential downstroke

The falling phase of the action potential is the result of two processes. One is the inactivation of voltage-gated Na^+ channels and the second is the activation of K^+ channels. One class of channels that plays a major role in controlling the rate of membrane repolarization are the sustained (i.e., delayed rectifier type) voltage-gated K^+ channels (Werz, M. A. and MacDonald, R. L., 1983). There appear to be at least three types of sustained voltage-gated K^+ currents present in sensory neurons based on biophysical and pharmacological properties

(Gold, M. S. *et al.*, 1996c). While the K^+ channel subunits underlying these currents have yet to be conclusively identified, immunohistochemical data have implicated several possible candidates (Rasband, M. N. *et al.*, 1998).

Another class of channel that contributes to membrane repolarization is the large conductance Ca^{2+}-modulated K^+ channel, (i.e., BK or Maxi-K channel). These channels are encoded by a single α-subunit (*slo*, which has several splice variants), whose gating properties, Ca^{2+} sensitivity, and pharmacological sensitivity is influenced by the presence of one of four distinct β-subunits (Wallner, M. *et al.*, 1998). While these channels have intrinsic voltage sensitivity, the voltage dependence of activation is such that in the absence of Ca^{2+}, it is unlikely that these channels would be sufficiently activated to contribute to the downstroke of the action potential (Wallner, M. *et al.*, 1998). This suggests that there is sufficient Ca^{2+} entry via voltage-gated Ca^{2+} channels during the action potential (Blair, N. T. and Bean, B. P., 2002), to enable activation of BK channels. The nature of the association between BK channels and voltage-gated Ca^{2+} channels in afferent terminals has yet to be described. However, the timing of BK current activation in the cell body suggests that there is a relatively tight association between the two.

5.04.2.3.3 After potential

The after potential is the change in membrane potential that follows an action potential. This is generally a membrane hyperpolarization (more negative than resting membrane potential), but may also be a depolarizing after potential (DAP). Two different mechanisms have been described that contribute to the DAP. One mechanism involves a high density of low threshold, or T-type voltage-gated Ca^{2+} channels (White, G. *et al.*, 1989). The biophysical properties of these channels are such that if present at a high enough density, they are able to depolarize the membrane following an action potential, providing enough depolarizing drive to evoke a burst of action potentials. The second current suggested to contribute to a DAP is a Ca^{2+}-dependent Cl^- current (Mayer, M., 1985). As the name implies, activation of this current requires sufficient Ca^{2+} entry during the action potential. It also requires the intracellular Cl^- concentration is such that the equilibrium concentration for Cl^- is depolarized.

In the majority of nociceptive sensory neurons, the somatic action potential is followed by an after hyperpolarization (AHP). In fact, a distinguishing feature of nociceptive afferents is that the somatic action potential is associated with a relatively long AHP (McLachlan, E. M. *et al.*, 1993; Villiere, V. and McLachlan, E. M., 1996; Djouhri, L. *et al.*, 2003a). A number of distinct currents have been suggested to influence the magnitude and duration of the AHP. Furthermore, because of differences between currents with respect to biophysical properties of channel gating, changes in intracellular Ca^{2+} concentrations, etc., the relative contribution of different ion channels to the AHP changes with time. Because of this feature, investigators have often divided the AHP into fast (early), intermediate, and slow (late) AHP. Channels mediating the fast AHP are generally those that contributed to the downstroke of the action potential (i.e., sustained voltage-gated K^+ and BK currents). These channels generally deactivate (i.e., close) rapidly and therefore do not generally contribute to the AHP for more than several of milliseconds (Fowler, J. C. *et al.*, 1985a).

The hyperpolarization associated with the fast AHP may result in the activation of three additional types of currents that have opposing influences on membrane potential. First, there may be the activation of inward rectifying K^+ currents (Scroggs, R. S. *et al.*, 1994). These currents appear to activate and inactivate rapidly in sensory neurons and therefore appear to primarily influence the fast AHP. Second, there may be the activation of low-threshold inactivating or A-type voltage-gated K^+ currents (Cardenas, C. G. *et al.*, 1995). These channels are largely inactivated at rest. However, there may be enough membrane hyperpolarization associated with the fast AHP to enable recovery from inactivation of a number of A-type K^+ channels. Because these channels have a low threshold for activation, once recovered from inactivation, the channels will open and therefore prolong the decay of the AHP. Because A-type currents in sensory neurons may inactivate slowly (i.e., with time constants of decay will over 100 ms (Gold, M. S. *et al.*, 1996c)), these channels can and do contribute significantly to the intermediate AHP (Harriott, A. *et al.*, 2006). As such, these channels play a significant role in regulating interspike interval (Connor, J. A. and Stevens, C. F., 1971; Yoshimura, N. and de Groat, W. C., 1999). Importantly, persistent inflammation and nerve injury have been shown to result in a decrease in these currents, which is associated with a concomitant increase in membrane excitability (Yoshimura, N. and de Groat, W. C., 1999; Moore, B. A. *et al.*, 2002; Stewart, T. *et al.*, 2003; Dang, K. *et al.*, 2004; Harriott, A.

et al., 2006). Third, there may be the activation of hyperpolarization-activated cationic current (Ih). These currents, carried by family channels called hyperpolarization-activated cyclic nucleotide-gated (HCN) channels, are nonselective cationic currents (Robinson, R. B. and Siegelbaum, S. A., 2003). Consequently, activation of these channels results in a depolarizing current, which, if of sufficient magnitude, may contribute to spike initiation. A high density of these channels can result in membrane oscillations and spontaneous activity. Indeed, there is evidence that these currents are upregulated in the presence of injury, a change that has been suggested to contribute to spontaneous afferent activity observed following nerve injury (Chaplan, S. R. *et al.*, 2003). Furthermore, there is evidence that blocking these channels attenuates mechanical hypersensitivity observed following nerve injury (Lee, D. H. *et al.*, 2005a). These channels are also modulated by cyclic nucleotides (Ingram, S. L. and Williams, J. T., 1994; Robinson, R. B. and Siegelbaum, S. A., 2003), which suggests that they may contribute to the increased excitability observed in the presence of inflammation as well, given that many inflammatory mediators induce an increase in cAMP concentrations (Levine, J. D. *et al.*, 1993).

In a subpopulation of sensory neurons, a slow AHP has also been described (Fowler, J. C. *et al.*, 1985a; 1985b; Weinreich, D. and Wonderlin, W. F., 1987). This AHP apparently reflects the activation of a Ca^{2+}-dependent K^+ channel that takes several hundred milliseconds to activate, but once activated takes several seconds to close (Cordoba-Rodriguez, R. *et al.*, 1999). Consequently, activation of these channels has a profound influence of spike accommodation. The slow AHP has been well described in nodose ganglion neurons, where it appears to be a target for inflammatory mediators that are able to block it in a cAMP dependent manner. The result is a dramatic increase in excitability (Weinreich, D. and Wonderlin, W. F., 1987). While there is evidence that a similar channel may be present in DRG neurons, it does not appear to play a major role in inflammatory mediator-induced sensitization of nociceptive afferents (Gold, M. S. *et al.*, 1996d). Four Ca^{2+}-dependent but voltage-independent channels have been cloned and are referred to as SK1–4, in reference to their small single-channel conductance (Bond, C. T. *et al.*, 2005). There is immunohistochemical evidence for the presence of these SK1 in sensory neurons (Boettger, M. K. *et al.*, 2002) and we have data from a single-cell PCR experiment suggesting that others are expressed as well (Gold, M. S., unpublished observation). It remains to be determined which if any of the SK channels mediates the slow AHP given several striking differences between the SK channels and the slow AHP in terms of pharmacological sensitivity, Ca^{2+} dependence and gating properties (Cordoba-Rodriguez, R. *et al.*, 1999).

5.04.2.3.4 Action potential threshold

The action potential threshold is where the various influences of all the ion channels in the membrane come into play. The magnitude and nature of leak conductance determines membrane resistance and the impact a generator current will have on the membrane potential. The biophysical properties of voltage-gated K^+ currents will determine the magnitude of the K^+ conductance associated with membrane depolarization as well as the impact of resting membrane potential on that value. Similarly, the biophysical properties of voltage-gated Na^+ currents will determine the voltage at which these channels begin to open, the rate at which they open and the rate at which they inactivate in the face of slow membrane depolarizations. Given the fact that there is considerable variation in the biophysical properties of Na^+ channels depending on which α- and β-subunits are present, the relative density of these subunits will have a significant impact on action potential threshold (Matzner, O. and Devor, M., 1992).

Another class of ion channels that may contribute to the action potential threshold are the low threshold (i.e., T-type) voltage-gated Ca^+ channels. As with voltage-gated Na^+ channels, T-type channels consist of an α-subunit that contains the channel-pore, voltage-sensing, and inactivation gates, and ancillary subunits that influence channel gating and trafficking (Catterall, W. A. *et al.*, 2005b). Three α-subunit genes have been cloned that encode for T-type currents. T-type currents appear to be present in a low density in putative nociceptive afferents (Scroggs, R. S. and Fox, A. P., 1992). While the activation rate of these channels does not appear to be sufficient to enable these channels to contribute to the action potential upstroke, the low threshold for activation enables these currents to amplify the effects of small membrane depolarizations. Consequently, an increase in the density of these channels can have a significant influence on membrane excitability. In support of this suggestion, these channels have recently been implicated in epileptogenisis (Czapinski, P. *et al.*, 2005). More recent

evidence suggests that they may contribute to the sensitization of nociceptive afferents in the presence of tissue injury (Barton, M. E. *et al.*, 2005).

5.04.2.3.5 High-threshold voltage-gated Ca^{2+} current

The structure of high-threshold voltage-gated Ca^{2+} channels is analogous to that of voltage-gated Na^{+} channels and T-type Ca^{2+} channels, with a single α-subunit that contains the ion pore, voltage-sensor, etc., and several different ancillary subunits that influence channel gating (i.e., the β-subunit) and/or channel trafficking (i.e., the $\alpha 2\delta$-subunit complex) (Catterall, W. A. *et al.*, 2005b). Seven α-subunits encoding high-threshold channels have been cloned, resulting in four currents that are distinguishable on the basis of unique pharmacological sensitivity. Molecular biological and pharmacological analyses indicate that all four current types are likely present in nociceptive afferents (Kostyuk, P. G. *et al.*, 1981; Scroggs, R. S. and Fox, A. P., 1992; Kim, D. S. *et al.*, 2001; Yusaf, S. P. *et al.*, 2001; Wu, Z. Z. *et al.*, 2004b). While these channels are critical for transmitter release, their role in direct regulation of excitability is less clear. On the one hand, they enable inward current that contributes to membrane depolarization and prolongation of the action potential. On the other hand, they enable activation of K^{+} and Cl^{-} currents that may be inhibitory. Thus, the site of channel activation is critical. Of note, in studies involving the isolated sensory neuron cell body, there is evidence to suggest that inflammatory mediators decrease the density of high-threshold voltage-gated currents (Borgland, S. L. *et al.*, 2002), and in the presence of nerve injury, there is a decrease in the density of high-threshold voltage-gated currents as well (Baccei, M. L. and Kocsis, J. D., 2000; Hogan, Q. H. *et al.*, 2000; Kim, D. S. *et al.*, 2001). Authors of both the studies suggested that these changes may contribute to pain associated with tissue injury and all are certainly correct on this point.

5.04.2.4 Membrane Receptors that Indirectly Alter Nociceptor Function

5.04.2.4.1 G-protein-coupled receptors

Many of the cell surface proteins that define the functional and histological identity of sensory neurons are the so-called GPCRs. These proteins, which possess seven transmembrane domains, an extracellular amino terminus, and an intracellular carboxyl terminus, signal by catalyzing the dissociation of guanosine diphosphate (GDP) from the α-subunit of heterotrimeric G proteins associated with the intracellular face of the plasma membrane. As a consequence of its dissociation, GDP is replaced with guanosine triphosphate (GTP), causing the heterotrimer to dissociate into a GTP-bound α-subunit and a free $\beta\gamma$ dimer. Both the GTP-bound α-subunit and the free $\beta\gamma$ dimer have specific cellular targets through which they are able to activate or inhibit signaling cascades and/or directly modify the activity of specific ion channels (Gilman, A. G., 1987; Pierce, K. L. *et al.*, 2002). This versatile signal transduction strategy is used by at least 1000 different GPCRs expressed throughout the body, and dozens of these are expressed by nociceptors and other sensory neurons. A few notable examples include B1 and B2 receptors for bradykinin (Steranka, L. R. *et al.*, 1988), P2Y2 receptors for ATP (Tominaga, M. *et al.*, 2001), PAR2 protease-activated receptors (Vergnolle, N. *et al.*, 2001), EP1 EP3C and EP4 receptors for prostaglandin E2 (Ferreira, S. H. *et al.*, 1978; Sugimoto, Y. *et al.*, 1994; Oida, H. *et al.*, 1995), mu, kappa, and delta opioid receptors (Dado, R. J. *et al.*, 1993; Arvidsson, U. *et al.*, 1995), several subtypes of metabotropic glutamate receptor (Bhave, G. *et al.*, 2001; Yang, D. and Gereau, R. W. T., 2002), and at least seven subtypes of 5HT receptor (Nicholson, R. *et al.*, 2003). One recently discovered family of apparently pronociceptive GPCRs are those of the so-called mrg or sensory neuron specific (SNS) family (Dong, X. *et al.*, 2001; Lembo, P. M. *et al.*, 2002; Zylka, M. J. *et al.*, 2003). The expression pattern of this GPCR family exhibits remarkable species-specific heterogeneity, as there appear to be at least 50 members in mice, but only four in rat and only a few distantly related homolog in humans (Zylka, M. J. *et al.*, 2003).

GPCRs expressed in sensory ganglia can be broadly classified into those that enhance nociceptor excitability and those that diminish it. Sensitizing receptors tend to couple to either Gq (e.g., B2, P2Y2, PAR2, and EP1) or Gs (e.g., EP3C, EP4). The activated α-subunit of Gq activates phospholipase C (PLC), an enzyme that catalyzes cleavage of the membrane phospholipid phosphatidylinositol bisphosphate to inositol 1,3,5-trisphosphate (IP3) and diacylglycerol (DAG). IP3 evokes the release of Ca^{2+} ions from intracellular stores that, together with DAG, go on to trigger the plasma membrane localization and activation of protein kinase C (PKC) (Gilman, A. G., 1987). Multiple PKC isoforms (α, δ, ε, and μ) have been shown to facilitate nociceptor

sensitization through their phosphorylation of ion channels and other target proteins (Cesare, P. *et al.*, 1999; Khasar, S. G. *et al.*, 1999; Olah, Z. *et al.*, 2002; Wang, Y. *et al.*, 2004). Ca^{2+} ions can also act in many other ways, such as by binding to proteins such as calmodulin that can allosterically regulate ion channels and intracellular enzymes in a Ca^{2+}-dependent manner (Numazaki, M. *et al.*, 2003). The GTP-bound Gαs subunit activates the enzyme adenylyl cyclase, which catalyzes the generation of cyclic adenosine monophosphate (cAMP) from ATP (Gilman, A. G., 1987). cAMP, in turn, activates cAMP-dependent protein kinase (protein kinase A, PKA), which can also phosphorylate and augment the responsiveness of certain ligand-, heat-, or voltage-gated channels (Gold, M. S. *et al.*, 1998; Bhave, G. and Gereau, R. W. T., 2004). Another intracellular enzyme recently implicated in nociception is the cAMP-activated guanine nucleotide exchange protein, Epac, which couples intracellular cAMP generation to the PLC-dependent sensitization of TTX-resistant sodium channels (Hucho, T. B. *et al.*, 2005). Interestingly, although all of the actions of pronociceptive GPCRs on excitability are indirect, through their actions on downstream signaling mechanisms, activation of some (e.g., bradykinin receptors) is sufficient to trigger action potential firing, whereas activation of others (e.g., prostaglandin receptors) primarily enhances neuronal responsiveness to other exogenous stimuli (Birrell, G. J. *et al.*, 1991; 1993; Kumazawa, T. *et al.*, 1996). This distinction may reflect differences in signal amplification or differences in the proximity of a given GPCR, its target enzymes, and a given depolarizing ion channel.

In contrast to the pronociceptive receptors, GPCRs that couple to Gi or Go proteins (e.g., μ-opioid receptor, type II metabotropic glutamate receptors) tend to suppress neuronal activity. This outcome results from inhibition of adenylyl cyclase (to diminish PKA phosphorylation of target proteins), inhibition of voltage-gated Ca^{2+} channels, and/or activation of hyperpolarizing G-protein-coupled inwardly rectifying K^+ channels (GIRKs of the Kv4 family) (McFadzean, I., 1988; Bhave, G. and Gereau, R. W. T., 2004).

5.04.2.4.2 Neurotrophin receptors

As described in detail elsewhere in this chapter, neurotrophins are also important regulators of sensory neuron development, survival, and excitability. One major class of neurotrophic factors that carry out these functions is the nerve growth factor (NGF) family (NGF, BDNF, neurotrophin-3, and neurotrophin-4). The receptors for this family of nociceptors fall into two categories: a low-affinity receptor p75, which appears to bind all members of the family, and homodimeric high-affinity receptors that are specific for each of the family members (TrkA, TrkB, or TrkC) (Huang, E. J. and Reichardt, L. F., 2001). Interestingly, one p75 monomer and one Trk dimer can apparently bind the same neurotrophin dimer simultaneously (He, X. L. and Garcia, K. C., 2004). During development, all sensory neurons destined to become nociceptors are dependent on NGF for survival. However, with maturation, only a subset of nociceptive afferents continues to express the high-affinity NGF receptor, TrkA. In these neurons, continued access to NGF is no longer necessary for survival, but remains essential for the maintenance of the afferent phenotype, which includes peptide expression and the specific composition of ion channels and transducers. Afferents have continued access to NGF produced by target tissue, but the amount of NGF available is critical: a decrease in access to NGF appears to result in the loss of nociceptive phenotype, while increased access to NGF results in an increase in the expression of nociceptive markers (Koltzenburg, M., 1999). BDNF and neurotrophin-3 can also alter nociceptor function (Shu, X. Q. and Mendell, M. L., 1999).

Transduction of the signal arising from the binding of NGF family members to their receptors consists of both slow processes requiring internalization of the neurotrophin–receptor complex and rapid signaling processes that occur at the nociceptor terminal. In both cases, NGF binding drives the dimerization of the TrkA receptor, resulting in TrkA autophosphorylation and the recruitment of a complex of molecules that signal through distinct enzymatic pathways. These include, but are not limited to, pathways involving phospho-inositol 3 kinase (PI3K), ras-mitogen-associated protein kinase (MAPK), and PLC γ. The activated complex with NGF-bound TrkA at its core is internalized into a specialized endosomal vesicle and transported along microtubules to the cell body, where signaling from this complex can trigger changes in transcription, translation, and protein trafficking (Zweifel, L. S. *et al.*, 2005). For many years, this slow retrograde process was viewed as the predominant mode of neurotrophin signaling in sensory neurons. More recently, however, it has become evident that NGF–TrkA activation of PI3K, MAPK, and PLCγ

produces rapid effects at the nociceptor terminal by altering ion channel sensitivity and plasma membrane localization within seconds, chiefly via receptor phosphorylation (Shu, X. and Mendell, M. L., 2001; Bonnington, J. K. and McNaughton, P. A., 2003; Zhang, X. *et al*., 2005). These events will be described in greater detail in the final section of this chapter. The p75 receptor is associated with the activation of a distinct set of second messenger pathways, including one involving the activation of sphingomyelinase and the liberation of ceramide (Zhang, Y. H. *et al*., 2002; Zhang, Y. H. and Nicol, G. D., 2004).

Nociceptive afferents expressing TrkA constitute a subpopulation of nociceptive afferents. Other subpopulations of nociceptive afferents express receptors for other neurotrophic factors. For example, one subpopulation of nociceptive afferents that do not express the neuropeptides substance P or CGRP, lose their NGF dependence during early postnatal life and begin to express a receptor for glial cell-derived neurotrophic factor (GDNF) (Molliver, D. C. *et al*., 1997). GDNF is a member of a second family of neurotrophins that includes neuturin, artemin, and persephin. As with NGF in TrkA-expressing neurons, the amount of GDNF to which these nonpeptidergic nociceptive afferents have access influences their phenotypic properties (see Fjell, J. *et al*., 1999a). GDNF signaling involves a specific GDNF family receptor (GFR), which acts in conjunction with another receptor tyrosine kinase, ret, that is shared by all members of this family. Interestingly, GDNF signaling involves second messenger pathways similar to those underling the actions of NGF, including PLC-γ, MAPK, and PI3K (Airaksinen, M. S. and Saarma, M., 2002). Thus, the phenotype of subpopulations of nociceptive afferents is regulated by different receptor systems that appear to ultimately use similar transduction cascades.

5.04.3 Additive and Emergent Properties of Nociceptor Membrane Proteins

5.04.3.1 Introduction

It should be evident from the preceding section that sensory afferents have, at their disposal, an extensive repertoire of cell surface proteins with diverse stimulus specificities and signaling capabilities. However, a full mechanistic understanding of nociceptive signal transduction, action potential generation, and spike propagation will require that pain biologists move beyond a mere itemization of the contents of this toolbox to an appreciation of the additive and emergent properties that can arise from the polymodal nature of some of these molecules, their posttranslational modulation, their interactions, and their spatial distribution. In this section, we attempt to illustrate these principles using a few specific examples, some well established, and others more speculative in nature.

5.04.3.2 Shared Modalities and Polymodality

One source of signaling complexity and heterogeneity among sensory neurons is the existence of multiple transducers for a given stimulus modality. For example, as described above, at least six TRP channels expressed in sensory neurons can be gated by heat or cold. Although each channel exhibits a characteristic temperature range over which it is thermally responsive, in many cases these ranges overlap, theoretically allowing continuous recognition of the thermal environment. At the same time, the largely nonoverlapping expression patterns of TRPM8, TRPV1, and TRPV2 lend some credence to the labeled-line hypothesis, which states that distinct sensory modalities (innocuous cold, pain, itch, etc.) are conveyed by anatomically distinct subsets of sensory afferents with specific central projection patterns (Craig, A. D., 2002). However, it should be noted that this segregation of thermotransduction mechanisms is not absolute. For example, some polymodal nociceptors exhibit paradoxical dual responsiveness to both intense heat and intense cold (Dodt, E. and Zotterman, Y., 1952). Even at the molecular level, TRPV1 and TRPA1 are coexpressed in a significant fraction of small-diameter sensory neurons. Though the implications for thermosensation remain controversial, such coexpression appears to be critical for full responsiveness to bradykinin, perhaps owing to the potentiation of TRPA1 by Ca^{2+} ions flowing through TRPV1 (Bautista, D. M. *et al*., 2006). Thus, while the labeled line hypothesis may adequately address some aspects of thermosensation, the overall situation may be more complex.

Mechanotransduction represents an even more extreme example of likely complementarity and redundancy among transducing molecules. Members

of both the ASIC and the TRP families have been implicated in this process, but only modest deficits in mechanotransduction have been reported in animals lacking any single putative mechanosensory protein (Price, M. P. *et al.*, 2000; Liedtke, W. and Friedman, J. M., 2003; Suzuki, M. *et al.*, 2003; Page, A. J. *et al.*, 2004; Kwan, K. Y. *et al.*, 2006). One interpretation of these findings is that mechanotransduction involves complexes of intracellular, transmembrane, and extracellular molecules, and that multiple interchangeable ion channel subunits can contribute to the ion permeation pathways of these transduction complexes.

Another source of complexity in sensory nerve signal transduction is responsiveness to multiple modalities within a single transduction molecule. One of the best-studied examples of this phenomenon is the capsaicin receptor, TRPV1. This channel protein can be activated by a diverse list of chemical or thermal stimuli (Caterina, M. J. and Julius, D., 2001). In addition, there is evidence that this channel or its splice variants may participate in osmotic or mechanical sensitivity in osmosensory regions of the brain and in non-neuronal cells of the urinary bladder (Birder, L. A., 2005; Naeini, R. S. *et al.*, 2006). Such polymodal responsiveness provides ample opportunities for convergent stimuli to combine additively or even supraadditively to produce greater nociceptor activation than any single stimulus. For example, even a modest reduction in pH (to 6.4) can drop the apparent thermal threshold for TRPV1 activation to near body temperature, possibly leading to spontaneous pain in the context of inflammation or ischemia (Tominaga, M. *et al.*, 1998).

5.04.3.3 Functional Interactions between Nociceptor Proteins

Interactions between different proteins on the surface of the nociceptor terminal can also have profound effects on nociceptors transduction and therefore function. Sometimes, these interactions are direct, as in the case of ion channel or GPCR heteromultimerization. In other cases, second messenger molecules and intracellular enzymes facilitate functional interactions among membrane proteins. Recently, for example, it was demonstrated that TRPM8 can activate Ca^{2+}-dependent phospholipases that, in turn, cleave the phosphatidyl inositol bisphosphate that inhibits or activates a host of channels, including inwardly rectifying potassium channels, as well as TRPM8, itself (Rohacs, T. *et al.*, 2005). Similarly, TRPV1 can activate MAPK signaling pathways (Zhuang, Z. Y. *et al.*, 2004). An additional interaction mechanism that has been reported in other types of sensory neurons, but could also conceivably occur in nociceptors, is the stimulation of Ca^{2+}-activated K^+ channels by the Ca^{2+} ions that flow through ligand-gated ion channels (Yuhas, W. A. and Fuchs, P.A., 1999; Isaacson, J. S. and Murphy, G. J., 2001). This arrangement has the potential to shape the amplitude, duration, and even the direction of generator potential.

Active membrane properties are also strongly dependent upon the interaction, at multiple levels, between the ion channels and the other membrane proteins underlying transduction and those regulating action potential initiation and propagation. For example, even small changes in resting membrane potential or generator potential will dramatically influence the availability of different voltage-gated ion channels. Similarly, the second messenger pathways activated by GPCRs and neurotrophin receptors can impact many facets of action potential generation and propagation, as described in the final section of this chapter. The spatial distribution of ion channels underlying each of the steps in afferent signaling is another critical determinant of whether or not there will be successful transmission of sensory information. The ion channels underlying spike initiation must be close enough to the ion channels underlying stimulus transduction that the generator potential pushes the membrane potential above the action potential threshold (Figure 1). Similarly, the ion channels underlying action potential propagation must be close enough to the site of spike initiation, that the action potential is faithfully propagated toward the central nervous system. In addition, action potential threshold may be relatively high in nociceptors that utilize the high-threshold voltage-gated Na^+ channel NaV1.8 for spike initiation, whereas action potential burst duration may be relatively short in nociceptors in which Ca^{2+}-dependent K^+ channels are present in high densities.

One implication of the precise nature of these spatial relationships between of ion channels within sensory neurons is that cellular processes underlying the trafficking and anchoring of ion channels within sensory neurons must be tightly regulated. While there is much to be learned about the distribution and anchoring of ion channels in sensory neurons, the observation that it is possible to induce modality

specific sensitization in polymodal nociceptors, raises the possibility that ion channels and/or transducers are differentially distributed throughout the terminal arbor. Adaptor/scaffold proteins can also shape nociceptor responsiveness by bridging ion channels or GPCRs with intracellular enzymes or with proteins that regulate intracellular transport. For example, PICK1, a PDZ domain-containing protein, appears to regulate the subcellular trafficking of ASIC channel subunits (Duggan, A. *et al.*, 2002), while annexin has been demonstrated to regulate surface expression and function of NaV1.8 (Okuse, K. *et al.*, 2002).

In summary, signaling heterogeneity, convergence of function, protein–protein interactions, and cytosolic signaling, as well as spatiotemporal organization of ion channels allow an already complex set of membrane proteins to vastly expand the sensory and coding capacity of nociceptive neurons.

5.04.4 Injury-Induced Plasticity in Transduction

5.04.4.1 Introduction

Research into the underlying mechanisms of pain associated with tissue injury has revealed that while there are a number of key players that are involved with a wide range of injury types the nature of the contribution of these players varies as a function of the type of injury. For example, acute, phosphorylation-dependent modulation of the voltage-gated Na^+ channel NaV1.8 (Fitzgerald, E. M. *et al.*, 1999), results in an increase in current that contributes to an inflammation-induced increase in nociceptors excitability (England, S. *et al.*, 1996; Gold, M. S. *et al.*, 1996b). In contrast, following traumatic nerve injury, redistribution of NaV1.8 to the axons of uninjured afferents appears to be necessary for the expression of mechanical hypersensitivity associated with nerve injury (Gold, M. S. *et al.*, 2003). There are many such examples, a number of which have been alluded to in the preceding discussion. However, while it is beyond the scope of the present chapter to detail the array of injury-induced changes in mechanisms underlying stimulus transduction, it is informative to consider several specific examples of modulatory events that occur in the context of inflammation and nerve injury. A few of these mechanisms are illustrated schematically in Figure 1.

5.04.4.2 Inflammation-Induced Changes in Nociceptor Sensory function – Inflammatory Pain

One of the best examples of injury-induced changes in the transduction properties of nociceptive neurons is the enhanced responsiveness to heat that occurs following tissue inflammation. As indicated in Section 5.04.2 of this chapter, the thermal hyperalgesia associated with several distinct inflammatory insults (CFA, carageenan, and mustard oil) or specific inflammatory mediators (bradykinin, NGF, ATP, proteases, and prostaglandin E2) depends strongly on the presence of TRPV1. Consistent with this observation, TRPV1 ion channel activity can be sensitized by these various agents in dissociated DRG neurons or heterologous expression systems (Lopshire, J. C. and Nicol, G. D., 1998; Shu,X. and Mendell, M. L., 2001; Vellani, V. *et al.*, 2001; Bonnington, J. K. and McNaughton, P. A., 2003). One lesson emerging from these studies, however, is that TRPV1 sensitization by inflammatory mediators can proceed via a number of alternative mechanisms.

The most direct mechanism by which inflammatory mediators can sensitize TRPV1 is by evoking the generation or liberation of TRPV1 coagonists, such as protons (Caterina, M. J. *et al.*, 1997) or arachidonic acid metabolites (Hwang, S. W. *et al.*, 2000; Huang, S. M. *et al.*, 2002). Convergent interactions of TRPV1 with multiple stimulators result in channel activity levels greater than those evoked by one agonist alone. Another extensively studied TRPV1 sensitization mechanism involves direct phosphorylation of this channel by serine/threonine kinases (PKC, PKA, Ca^{2+}/calmodulin-dependent protein kinase II) (Bhave, G. and Gereau, R. W. T., 2004) or the src tyrosine kinase (Zhang, X. *et al.*, 2005). Although there is some overlap in their recognition sequences, each kinase apparently targets a different collection of phosphorylation sites, resulting in the generation of distinct phospho-TRPV1 species. In the case of ser/thr kinases, phosphorylation appears to enhance TRPV1 sensitivity to its chemical and thermal agonists and/or reverse TRPV1 desensitization (Bhave, G. and Gereau, R. W. T., 2004). In contrast, TRPV1 phosphorylation by src kinase, which is activated by NGF–trkA signaling, leads within 10 min to a translocation of TRPV1 from an intracellular compartment to the plasma membrane, resulting in an increase in the overall number of TRPV1 channels on the cell surface (Zhang, X.

et al., 2005). The MAPK, p38, has also been shown to participate in NGF-stimulated facilitation of TRPV1 signaling during inflammation. Although the relevant target of p38 phosphorylation is not known, the end result is an apparent enhancement of TRPV1 translation and/or trafficking to peripheral nociceptor terminals that requires 1–2 days (Ji, R. R. *et al.*, 2002).

A third general mechanism by which TRPV1 can be modulated in the context of inflammation is by alterations in membrane phospholipid content. For example, it has been proposed that phosphatidylinositol bisphosphate exerts a tonic inhibition on TRPV1 activity and that its hydrolysis by PLC relieves that inhibition (Chuang, H. H. *et al.*, 2001; Prescott, E. D. and Julius, D., 2003). The effects of PIP2 on TRPV1 may be complex, however, given that this phospholipid is also required for resensitization of TRPV1 following agonist-dependent desensitization (Liu, B. *et al.*, 2005). More recently, work from several laboratories has provided evidence that phosphorylation of PIP2 to PIP3 by PI3 kinase to form PIP3 represents yet another mechanism for TRPV1 sensitization (Bonnington, J. K. and McNaughton, P. A., 2003; Zhuang, Z. Y. *et al.*, 2004; Zhang, X. *et al.*, 2005). Although the precise basis for this effect remains unclear, one intriguing suggestion is that it is due to the effects of PIP3 on src activity, thus potentially linking lipid-based and protein kinase-based sensitization events (Zhuang, Z. Y. *et al.*, 2004). Much remains to be learned about the relative importance of and interactions between these different processes. However, it is clear that nociceptors have developed multiple means of responding to tissue inflammation by becoming hypersensitive.

5.04.4.3 Changes in Nociceptor Function Following Traumatic Nerve Injury – Neuropathic Pain

Pain and hyperalgesia arising from direct damage to sensory neurons come under the heading of neuropathic pain. One of the most dramatic and common features of neuropathic pain is the presence of ongoing pain (Backonja, M. M. and Stacey, B., 2004). This feature is distinct from inflammatory pain, where it is often possible to relieve pain if it is possible to eliminate stimuli that impact the inflamed tissue. There is compelling evidence to suggest that ongoing pain associated with peripheral nerve injury is the result of aberrant and/or ongoing activity in both injured afferents and their uninjured neighbors (Gold, M. S., 2000b). Most compelling are the observations that ongoing neuropathic pain may be blocked with the administration of local anesthetics (Gracely, R. H. *et al.*, 1992). However, there is also a very tight correlation between the development of nociceptive behaviors and the emergence of ongoing afferent activity in animal models of neuropathic pain (Liu. C. N. *et al.*, 2000). Because of this association between ongoing afferent activity and ongoing pain, considerable effort has been dedicated to the identification of mechanisms that may contribute to this activity. Central to this search is the question of whether the activity is driven by stimulus transduction, or whether there are changes in the relative contribution of ion channels resulting in membrane potential instability, the emergence or amplification of membrane potential oscillations that are capable of driving action potential generation. There is evidence for both sources of activity.

5.04.4.3.1 Nerve injury-induced changes in transduction

Several nerve injury-induced changes in transduction have been identified. These can be loosely grouped into those involving aberrant expression of transducers normally present in peripheral nerve, aberrant coupling between the transducers and cellular pathways and the emergence of inappropriate sources of stimulation. The list of tranducers aberrantly expressed following nerve injury has grown as fast as transducers have been identified. Aberrant expression comes in at least three forms. One is the expression of transducers in the wrong place within a neuron. The most dramatic example of this is the emergence of mechanical and thermal sensitivity at the cut end of a peripheral axon (Michaelis, M. *et al.*, 1999). More recently, it have been demonstrated that compression of a nerve is sufficient to alter the distribution of tranducers in the membrane (Ma, C. *et al.*, 2006). Importantly, aberrant expression patterns are not restricted to the point of compression or injury as a cut axon will result in increased mechanical sensitivity of the sensory neuron soma (Howe, J. F. *et al.*, 1977). Two consequences of these changes are the emergence of mechanical sensitivity at sites that are normally mechanically insensitive and mechanical allodynia, a situation in which a mechanical stimulus, such as that associated with movement, that is normally not painful, becomes a source of pain. Worse still, mechanical stimuli associated with physiological functions, such as movement of tissue associated with blood flow, may also become a source of stimuli for these transducers. A

second form of aberrant expression is the emergence of transducers in the wrong neurons. For example, as indicated above, TRPV1 is primarily expressed in nociceptive afferents. However, following nerve injury, this transducer is expressed in what were previously low-threshold non-nociceptive afferents (Rashid, M. H. *et al.*, 2003). A third form of aberrant expression is a change in the levels of expression of transducers normally present in a neuron. There is evidence for both decreases in inhibitory transducers and increases in excitatory transducers. For example, nerve injury is associated with a decrease in the expression of opioid receptors (Kohno, T. *et al.*, 2005), which are the transducers for the inhibitory signal of both endogenous and exogenous opioids. The result is a decrease in the efficacy of mechanisms normally involved in attenuating pronociceptive processes. An example of an increase in an excitatory transducer is an increase in the expression of the ATP receptor, P2X3 (Fukuoka, T. *et al.*, 2002). The combination of these changes in expression levels is a net increase in afferent excitability.

Evidence in support of aberrant coupling between transducers and signaling pathways following nerve injury is less compelling but should be mentioned. The pathway that has received the greatest attention is the adrenergic system, largely as a result of the observation that pain associated with nerve injury may be sympathetically dependent. What most pain scientists agree on, is that in normal tissue, activation of the sympathetic nervous system is not painful. In fact, primary afferent neurons express adrenergic receptors that are critical for the antinociceptive actions of spinally administered adrenergic agonists. However, following nerve injury, adrenergic agonists may become excitatory (Sato, J. and Perl, E. R., 1991; Devor, M. *et al.*, 1994; Chen, Y. *et al.*, 1996; Liu, X. *et al.*, 1999; Moon, D. E. *et al.*, 1999). Mechanisms of this excitation are still debated, but there is evidence to support at least two mechanisms. One is that there is a change in adrenergic receptor expression and/or coupling such that activation of adrenergic receptors on primary afferent becomes excitatory (Davis, K. D. *et al.*, 1991; Birder, L. A. and Perl, E. R., 1999). A second is that there is a change in the signaling pathway underlying the actions of adrenergic agonists at autoreceptors on the sympathetic postganglionic neuron terminals: in the presence of elevated levels of intracellular Ca^{2+}, norepinephrine becomes capable of driving the release of arachidonic acid metabolites such as prostaglandin E2 (Gonzales, R. *et al.*, 1989; 1991), which then act directly on the primary afferent.

The emergence of inappropriate sources of stimulation may involve sources that are both expected and those that are much less so. Following nerve injury, there are a number of changes that occur in both the injured axon and the surrounding tissue that facilitate restoration of the normal innervation pattern (see Murinson, B. B. *et al.*, 2005). Injured nerves extend processes, which if scar tissue forms at the same time, may not be able to access former nerve tracks. The result may be the formation of a neuroma. Thus, an expected source of stimulation would be mechanical stimulation of the neuroma associated with traction of the surrounding scar tissue. Interestingly, nerve injury may also be associated with the sprouting of sympathic postganglionic terminals into the sensory ganglia (McLachlan, E. M. *et al.*, 1993). This striking observation provided anatomical evidence of sympathic/afferent coupling within the sensory ganglia. While many details about the mechanisms underlying this sprouting have yet to be determined, access to NGF appears to be a regulating factor (Ramer, M. S. and Bisby, M. A., 1999).

5.04.4.3.2 Changes in membrane stability

As emphasized above, the distribution, expression levels and biophysical properties of ion channels in a neural membrane are critical to the maintenance of a given level of membrane excitability. Change in any of these parameters may have profound effects. Not surprisingly, nerve injury is associated with changes in all three, with clear examples of changes in distribution (Gold, M. S. *et al.*, 2003), expression levels (Waxman, S. G. *et al.*, 1994; Dib-Hajj, S. *et al.*, 1996; Decosterd, I. *et al.*, 2002), and biophysical properties (Cummins, T. R. and Waxman, S. G., 1997) of ion channels in both injured neurons and their uninjured neighbors. One of the more striking ramifications of changes in all three of these properties is the emergence and/or amplification of membrane potential oscillations which, it has been argued, are sufficient to drive ongoing activity following nerve injury (Amir, R. *et al.*, 1999). Two critical players have been identified. One is a voltage-gated Na^+ channel with appropriate biophysical properties to sustain the upstroke of the oscillation. The second is a K^+ leak current that drives the downstroke of the oscillation (Amir, R. *et al.*, 1999). While the K^+ channels have yet to be identified, several different Na^+ channels have been implicated. One possibility is a TTX-resistant channel such as NaV1.8 or NaV1.9. This would be consistent with the observation that the upstroke of the oscillation in

trigeminal neurons is TTX-resistant (Puil, E. *et al.*, 1989) as well as the biophysical properties of the current implicated in studies of isolated DRG neurons (Liu, C. N. *et al.*, 2002). However, spontaneous activity in injured afferents is most robust in sensory neurons with a large cell body diameter giving rise to myelinated axons (Liu, C. N. *et al.*, 2000); neither TTX-resistant channel is present in this subpopulation of sensory neurons and both are dramatically downregulated in injured neurons (Dib-Hajj, S. *et al.*, 1996; Decosterd, I. *et al.*, 2002). Another channel that has received a lot of attention is NaV1.3. This channel is upregulated in the presence of injury (Waxman, S. G. *et al.*, 1994; Black, J. A. *et al.*, 1999) and appears to have biophysical properties consistent with ongoing high-frequency activity (Cummins, T. R. and Waxman, S. G., 1997; Cummins, T. R. *et al.*, 2001). There is evidence for the accumulation of TTX-sensitive Na^+ channels at sites of nerve injury (Devor, M. *et al.*, 1993). Furthermore, there is evidence that at least some of the oscillatory activity in sensory neurons is sensitive to TTX (Amir, R. *et al.*, 1999). However, antisense knockdown of this channel has no impact on nociceptive behavior associated with nerve injury (Lindia, J. A. *et al.*, 2005).

Recent evidence from a cohort of individuals who suffer from a paroxysmal pain disorder raise the possibility that NaV1.7 may contribute to nerve injury-induced increases in afferent excitability. Sufferers of this disorder appear to share gain of function mutations in NaV1.7, decreasing the rate and/or extent of channel inactivation (Fertleman, C. R. *et al.*, 2006). While the link between neuropathic pain and paroxysmal pain disorder is tenuous, manifestations of this disorder share similarities with signs and symptoms neuropathic pain, most notably a sensitivity to the membrane stabilizer carbamazepine. A different set of NaV1.7 mutations appears to underlie primary erythermalgia (Yang, Y. *et al.*, 2004), a rare pain disorder associated with pain and redness in the feet and hands. Mutations in NaV1.7 associated with erythermalgia contribute to an increase in the excitability of primary afferent neurons (Rush, A. M. *et al.*, 2006), but they also appear to result in a decrease in the excitability of sympathetic postganglionic neurons, and it is likely the combination of these changes in excitability that appear to mediate the unique symptoms of the disorder. At least two lines of evidence argue against a role for NaV1.7 in pain associated with traumatic nerve injury. First, in patients with peripheral nerve injury NaV1.7 protein appears to decrease in the DRG neurons and remains undetectable in injured peripheral nerve (Coward, K. *et al.*, 2001). Second, there appears to be no deficit in the nerve injury-induced hypersensitivity in an NaV1.7 null mutant mouse (Nassar, M. A. *et al.*, 2005). Thus, while the specific channels underlying nerve injury-induced increases in afferent excitability have yet to be conclusively identified, it is clear that ion channels alone may become a generator of ongoing activity in injured neurons.

5.04.4.3.3 Mechanisms underlying nerve injury-induced changes in transduction

While many of the mechanistic details underlying nerve injury-induced changes in transducer and/or ion channels have yet to be identified, it is clear that changes in access to trophic factors plays a major role in the process (Waxman, S. G. *et al.*, 1999; Sah, D. W. *et al.*, 2003). Following nerve injury, different groups of afferents may either be deprived of access to neurotrophic factors or bathed in excess levels with those that are injured being deprived and those that remain being bathed in excess. The suggestion that access to neurotrophic factors plays a critical role in driving nerve injury-induced changes is supported by the observation that exogenous application of factors such as NGF or GDNF to injured neurons restores ion channel expression levels and may eliminate ongoing activity. Exogenous NGF restores expression levels of NaV1.8 and NaV1.9 and reduces expression levels of NaV1.3 (Black, J. A. *et al.*, 1997; Fjell, J. *et al.*, 1999b). GDNF has also been shown to differentially regulate expression levels of NaV1.3 (Boucher, T. J. *et al.*, 2000; Leffler, A. *et al.*, 2002). Similarly, the peripheral administration of NGF results in the sensitization of nociceptive afferents and increases in the expression of many proteins that are increased in uninjured afferents following nerve injury (e.g., TRPV1) (Ji, R. R. *et al.*, 2002; Rashid, M. H. *et al.*, 2003). Attenuation of neurotrophin signaling through antibodies or antagonist has also been shown to reverse inflammation-induced changes in afferent excitability (McMahon, S. B., 1996; Koltzenburg, M. *et al.*, 1999).

5.04.5 Conclusion

Adequate treatment of chronic pain in the absence of serious side effects remains an elusive goal for patients, clinicians, and basic researchers. What should be clear from the preceding discussion is that the identification of effective therapeutic interventions has been hampered by the realization that the system is far more

complex than ever imagined. The redundancy of signaling molecules, the promiscuity of receptors, and the delicate balance of both inhibitory and facilitatory processes have all kept the silver bullet frustratingly out of reach. However, identification of proteins highly enriched in nociceptive afferents that are critical for the transmission of nociceptive information to the central nervous system, an understanding of how these molecules function within the larger context of molecules in and around the afferent, all coupled with the early success of selective blockers of these compounds in clinical trials, suggests that truly novel and effective therapeutic interventions may not be far off.

Glossary

allodynia Painful response to normally pain-free stimulus on the skin.

herpes zoster (HZ) Usually painful reactivation of varicella-zoster virus.

postherpetic neuralgia (PHN) Prolonged pain after herpes zoster.

varicella-zoster virus (VZV) The causative agent of herpes zoster.

5.05.1 Epidemiology and Course of Herpes Zoster and Postherpetic Neuralgia

Postherpetic neuralgia (PHN) is a painful aftermath of herpes zoster (HZ), an acute inflammation of spinal nerves due to reactivation of varicella-zoster virus (VZV) residing dormant in sensory ganglia. HZ is the most common neurological disorder with a cumulative lifetime incidence of 10–20% in general population, and as high as 50% of a cohort surviving to 85 years of age (Dworkin, R. H. and Schmader, K. E., 2001). Surveys from two United Kingdom general-practice populations reported annual incidence rates of 3.4–4.8 per 1000 persons (McGregor, R. M., 1957; Hope-Simpson, R. E., 1965). Two population-based studies of epidemiology of HZ have been published from Rochester, Minnesota (Ragozzino, M. W. *et al.*, 1982; Donahue, J. G. *et al.*, 1995) and reported the annual age-adjusted incidences of 1.3 and 2.1 per 1000. About 50% of the HZ cases are thoracic, whereas trigeminal, cervical, and lumbar locations represent each 10–15% of the cases and sacral dermatomes about 5% of the cases. The distribution of HZ reflects the initial virus burden to sensory ganglia (Hope-Simpson, R. E., 1965).

In HZ, viral replication first causes ganglionitis followed by infection of the corresponding nerve and skin dermatome. Pain and unilateral dermatomal rash are the typical symptoms, often accompanied by paresthesias and itching. Patients with HZ affecting the extremities can have complex regional painlike symptoms (color changes, skin temperature changes, edema, weakness, and extradermatomal involvement), and the risk of PHN is high in these cases (Berry, J. D. *et al.*, 2004). Most patients experience pain during HZ, with only about 10% remaining pain-free. Pain precedes rash in 75% of cases (Haanpää, M. *et al.*, 1999a; Chidiac, C. *et al.*, 2001), lasting usually for some days, but in some cases weeks and even months before the eruption of rash (Gilden, D. H. *et al.*, 1991). Zoster pain tends to resolve spontaneously with time, but a minority of patients continue to have pain after the healing of rash. Retrospective epidemiological studies based on help-seeking behavior reported that about 10% of the patients have pain after the healing of rash, 5% of the patients have pain at 3 months, and 2% have pain at 1 year (Burgoon, C. F. *et al.*, 1957; Hope-Simpson, R. E., 1965; Ragozzino, M. W. *et al.*, 1982). A prospective long-term follow-up study from Iceland reported that 19% of the patients have pain at 1 month, 7% at 3 months, and 3% at 1 year (Helgason, S. *et al.*, 2000). A prospective observational community study reported pain in 30% of the patients at 6 weeks, 27% at 12 weeks, 16% at 6 months, and 9% at 1 year (Scott, F. T. *et al.*, 2003). The most important risk factors for PHN are old age and severe acute pain. Other predictors of PHN are severe rash, presence of prodromal pain, viremia at

presentation (Scott, F. T. *et al.*, 2003), and more pronounced immune response (Sato-Takeda, M. *et al.*, 2004), which reflect more severe acute disease. Mechanical allodynia, that is, painful response to normally pain-free mechanical stimulus on the skin, and pinprick hypoesthesia in acute HZ are associated with PHN at 3 months, but due to their insufficient sensitivity and specificity, they cannot be used as predictors of PHN for an individual patient (Haanpää, M. *et al.*, 2000). Abnormal findings in quantitative sensory testing (QST) are common in HZ: warm and cold thresholds are elevated in 20%, heat pain thresholds are lowered in 10%, and tactile thresholds are elevated in 25% of the patients with HZ. All somatosensory abnormalities tend to normalize with time. The abnormal QST findings are associated neither with the severity of acute pain nor with the development of PHN (Haanpää, M. *et al.*, 1999b).

HZ has been regarded as a simple model of peripheral unilateral neuritis caused by VZV, but evidence from neuropathological reports suggest that viral invasion and inflammation may extend to the central nervous system (CNS) as well (Denny-Brown, D. *et al.*, 1944; Watson, C. P. N. *et al.*, 1991). In a study with 56 immunocompetent HZ patients without clinical symptoms of CNS infection, cerebrospinal fluid (CSF) samples were obtained from 46 patients on days 1–18 from the eruption of rash, and 16 consecutive patients with cranial or cervical HZ underwent magnetic resonance imaging (MRI) 1–5 weeks following rash (Haanpää, M. *et al.*, 1998). In 35% of the patients there was evidence of VZV in the CSF either in the form of a positive polymerase chain reaction (PCR) or anti-VZV-immunoglobulin G (IgG). Leucocytosis (range 5–1440 μL^{-1}) was found in 46% of the patients. These changes were more common in patients with complications (e.g., peripheral motor paresis or ophthalmic complications) but they did not predict PHN. Zoster-related MRI changes were found in the brainstem in 56% of the patients and in the cervical cord in two. Three patients had enhancement of the trigeminal nerve in addition to the brainstem lesions. The presence of brainstem lesions in MRI was associated with the development of PHN at 3 months but not with the severity of acute pain.

Those who continue to suffer from prolonged pain after HZ describe three types of pain: a constant deep aching or burning pain, an intermittent pain with a lancinating quality, and allodynia of the skin. In an individual patient, any component can be the most distressing feature of the pain. Itching and dysesthetic sensations may also be present, being in some patients even more annoying than the pain itself (Oaklander, A. L. *et al.*, 2003). Normal sensory function is often altered in PHN. Mechanical allodynia is reported in 65–87% of patients with PHN (Watson, C. P. N. *et al.*, 1988; Nurmikko, T. and Bowsher, D., 1990; Pappagallo, M. *et al.*, 2000), and some patients have cold allodynia (Bowsher, D., 1996). The patients may experience paradoxical sensations in the affected skin area: hot may be felt cold or vice versa, and although light touch may be unpleasant or painful, firm pressure may attenuate pain (Nurmikko, T., 1994). Noordenbos W. (1959) investigated the skin of the patients with PHN and noted that there were areas of major sensory loss as well as minimal sensory loss in the affected region. Others have suggested that extreme allodynia to light touch is often restricted to areas surrounding scarred skin or lying at the border of affected and unaffected dermatomes. Allodynic areas may be often warm termographically, while scarred areas with maximal sensory loss are cool (Rowbotham, M. C. and Fields, H. L., 1989). When tested with conventional clinical methods, hypoesthesia to touch was present in 90% and hypoesthesia to pinprick in 92% of the patients in a pain clinic series (Watson, C. P. N. *et al.*, 1988). In another case series, 94% of the patients had impaired temperature and/or pinprick sensation and/or allodynia, and about 33% had also tactile deficit (Bowsher, D., 1996).

In QST, marked threshold elevations within the affected dermatome compared with the mirror-image site have been found for touch, pinprick, vibration, warmth, and cold (Bjerring, P. *et al.*, 1990; Nurmikko, T. and Bowsher, D., 1990; Eide, P. K. *et al.*, 1994; Rowbotham, M. C. and Fields, H. L., 1996; Rowbotham, M. C. *et al.*, 1996a; Choi, B. and Rowbotham, M. C., 1997; Attal N. *et al.*, 1999; Pappagallo, M. *et al.*, 2000). This indicates damage to unmyelinated and myelinated sensory fibers. Heat pain hypoesthesia is common in patients with PHN, but a minority of patients has heat pain hyperalgesia (Nurmikko, T. and Bowsher, D., 1990; Rowbotham, M. C. and Fields, H. L., 1996; Rowbotham, M. C. *et al.*, 1996a; Choi, B. and Rowbotham, M. C., 1997). In some patients with PHN, no asymmetry was found in warmth or heat pain thresholds, while the greatest threshold difference observed between the affected and contralateral dermatomes was as high as 12.2 °C for warmth and 9.6 °C for heat pain (Choi, B. and Rowbotham, M. C., 1997). However, noticeable asymmetry in thresholds between the affected site

and its mirror-image site was found in different modalities from 5% to 13% of HZ patients not developing PHN (Nurmikko, T. and Bowsher, D., 1990). Hence, it seems possible to have sensory threshold abnormality without PHN, and PHN without sensory threshold abnormality in the affected dermatome after HZ.

5.05.2 Neuropathology of Herpes Zoster and Postherpetic Neuralgia

The classic report of Head H. and Campbell A. W. (1900) is the most comprehensive study of the neuropathology of HZ, but it does not report the possible presence of PHN. Despite it and later studies, our understanding of the pathophysiology of PHN is far from complete. In acute HZ the dorsal root ganglion shows hemorrhagic inflammation and subsequent scarring (Head, H. and Campbell, A. W., 1900; Denny-Brown, D. *et al.*, 1944; Reske-Nielsen, E. *et al.*, 1986; Schmidbauer, M. *et al.*, 1992). Typically, only one ganglion is severely affected, while mild patchy inflammatory changes can be found in the neighboring ganglia (Denny-Brown, D. *et al.*, 1944; Schmidbauer, M. *et al.*, 1992). Ganglion cell necrosis is followed by secondary degeneration and fibrosis in the sensory root and the peripheral nerve. Direct inflammation can also damage the root and nerve (Head, H. and Campbell, A. W., 1900; Denny-Brown, D. *et al.*, 1944; Zacks, S. L. *et al.*, 1964; Watson, C. P. N. *et al.*, 1991; Schmidbauer, M. *et al.*, 1992). VZV has been shown in ganglial and satellite cells; in damaged nerve roots; in the vasa nervorum; in the distal peripheral nerve endoneurally, perineurally, and epineurally; and in Schwann cells (Schmidbauer, M. *et al.*, 1992). Inflammation in peripheral nerves may persist from weeks to months, which can eventually lead to noticeable fibrosis (Head, H. and Campbell, A. W., 1900; Zacks, S. L. *et al.*, 1964; Watson, C. P. N. *et al.*, 1991).

Only a few studies compare the neuropathological findings of those who recover with the finding of those who have PHN. In four patients who had HZ and went on to develop PHN, atrophy of the dorsal horn was found at autopsy whereas those without PHN did not show similar changes (Watson, C. P. N. *et al.*, 1991). However, one patient without PHN showed subacute myelopathy. The investigators found no difference in substance P, calcitonin gene-related peptide, a marker for norepinephrine, or in opioid receptor binding studies (Watson, C. P. N. *et al.*, 1991). After HZ, a preponderance of small-diameter fibers in the surviving fiber population in peripheral nerves is suggested (Noordenbos, W., 1959; Zacks, S. L. *et al.*, 1964; Watson, C. P. N. *et al.*, 1991), but the significance of this finding is ambiguous, as the fibers in question have not been fully identified. Loss of myelin combined with the preservation of axons has also been described (Fabian, V. A. *et al.*, 1997). Loss of axons and myelin in the peripheral nerve is similar in cases with and without PHN (Zacks, S. L. *et al.*, 1964).

Three studies using skin biopsies report that HZ lowers the innervation density of skin (Rowbotham, M. C. *et al.*, 1996a; Oaklander, A. L. *et al.*, 1998; Oaklander, A. L., 2001). These changes are more profound in patients with PHN, possibly because the absence of pain requires the preservation of a minimum density of primary nociceptive neurons (Oaklander, A. L., 2001). The severity of allodynia is nevertheless associated with well-preserved fiber density (Rowbotham, M. C. *et al.*, 1996a). The results of Oaklander A. L. *et al.* (1998) suggest that unilateral HZ can cause bilateral segmental damage to primary sensory neurons. It is of interest that changes in the epidermal innervation in the contralateral unaffected skin in patients with PHN correlate with the presence and severity of pain, but the pathophysiological explanation for this is unknown.

5.05.3 Mechanisms of Acute Zoster Pain

Mechanisms of acute zoster pain are not fully established. It is obvious that acute zoster pain represents a combination of nociceptive and neuropathic pain. The nociceptive component is caused by inflammation of the skin, which leads to excitation and sensitization of nociceptors. Increased afferent activity transmitted to the spinal cord creates a state of central hyperexcitability in the dorsal horn neurons, which resolves gradually in concert with the healing of tissue damage in a majority of patients. The neuropathic component is caused by direct viral damage and inflammation in the dorsal ganglion, peripheral nerve, and in some cases also in the dorsal root and spinal cord. According to the study of acute HZ, preherpetic pain is not associated with the severity of rash or QST changes, which suggests that virus-induced irritation in the afferent pathways rather than dermal inflammation or axonal damage is more salient in preherpetic pain (Haanpää, M. *et al.*, 1999a).

Because the abnormal QST findings are not associated with the severity of acute zoster pain, dysfunction of the thin fibers per se seems not to be the dominating factor in acute zoster pain. The presence of severe acute pain in acute HZ is associated with the presence of mechanical allodynia but not with severe rash, which implies a neuropathic character of allodynia in acute HZ rather than hyperesthesia or hyperalgesia due to cutaneous inflammation (Haanpää, M. *et al.*, 2000). It is not known to what extent the mechanisms of allodynia in acute HZ are the same as the mechanisms of allodynia in PHN. The extension of allodynia and somatosensory changes outside the affected dermatome is not uncommon in acute HZ, which indicates that the CNS is quite frequently involved even in mild cases of HZ (Haanpää, M. *et al.*, 1999a; 1999b; 2000). Although QST changes are common in HZ, they are not associated with the development of PHN. Hence, the prolonged pain in HZ cannot be explained by as a simple consequence of either axonal damage (represented as threshold elevation) or sensitization of the nociceptive system (represented as heat pain hyperalgesia). Transition from acute zoster-associated pain to PHN is likely to be a multifactorial process, perhaps involving both peripheral and central changes. The genetic factors regulating the inflammatory responses may play an important role in this process (Sato-Takeda, M. *et al.*, 2004).

5.05.4 Pathophysiology of Postherpetic Neuralgia

Patients with PHN have been studied using quantitative testing of the primary afferent function, skin biopsies, and controlled treatment trials. In studies of patients with allodynic PHN, the results concerning the role of C-nociceptors in PHN are conflicting. Using indirect assessment of C-fibers by quantifying the axon reflex reactions induced by histamine iontophoresis, Baron R. and Saguer M. (1993) found that histamine responses were reduced or abolished within allodynic areas, indicating degeneration of C-fibers. Patients, who had recovered from HZ without PHN, had bilaterally identical histamine responses, indicating complete recovery of C-fibers. Additionally, impairment of the C-fiber function correlated positively with the intensity of postherpetic pain. In contrast, Rowbotham M. C. and Fields H. L. (1996) found, using QST measurements, that in the allodynic area of PHN patients, pain severity correlated with the preservation of thermal sensory function. The same conclusion was drawn from the study using skin punch biopsies; the loss of cutaneous innervation correlated inversely with allodynia, and pain intensity was strongly related to the severity of allodynia (Rowbotham, M. C. *et al.*, 1996a). In another study, significant correlation was found between the intensity of ongoing pain and mechanical allodynia in patients with short-lasting (<1 year) but not in patients with long-lasting (≥1 year) PHN (Pappagallo, M. *et al.*, 2000). According to these results, the underlying pathophysiology may vary from patient to patient and with the duration of PHN.

In PHN, three subtypes have been suggested (Table 1): the irritable nociceptor subtype, the deafferented allodynic subtype, and the deafferented nonallodynic subtype (Fields, H. L. *et al.*, 1998; Petersen, K. *et al.*, 2000; Rowbotham, M. and Petersen, K., 2001). In patients with anatomically intact primary afferent nociceptors, pain and allodynia may be due to abnormal hyperactivity of the nociceptors and subsequent central sensitization, respectively (irritable nociceptor type). The topical capsaicin application test can be used to identify PHN patients in whom the mechanism of pain involves sensitization of peripheral afferents (Petersen, K. *et al.*, 2000;

Table 1 Proposed subtypes of PHN

Subtype	*Thermal sensory deficit*	*Allodynia*	*Anesthetic infiltration*	*Capsaicin sensitivity*
Irritable nociceptors	Minimal deficit or hyperalgesic to heat pain	Marked	Prolonged relief	Severe burning pain
Deafferented nonallodynic subtype	Marked to all modalities	None	No change	No sensation
Deafferented allodynic subtype	Marked to all modalities	Variable	Relief of allodynia short duration	Variably reduced

Fields, H. L., Rowbotham, M., and Baron, R. 1998. Postherpetic neuralgia: irritable nociceptors and deafferentation. Neurobiol. Dis. 5, 209–227 and Rowbotham, M. C., Petersen, K. L., and Feilds, H. L. Is postherpetic neuralgia more than one disorder. 1999. IASP New. Let. 3–7.

Petersen, K. *et al.*, 2002). In patients with loss of cutaneous C-nociceptor function, evaluated either by using QST of thermal thresholds (Nurmikko, T. and Bowsher, D., 1990; Nurmikko, T., 1994; Choi, B. and Rowbotham, M. C., 1997), C-fiber axon reflex (Baron, R. and Saquer, M., 1993), or capsaicin-induced flare (Morris, G. C. *et al.*, 1995), deafferentation and central reorganization may explain the PHN pain (Fields, H. L. *et al.*, 1998). If tactile (Aβ) fibers are preserved, allodynia may result from sprouting of the spinal terminals of Aβ mechanoreceptors into contact with the pain transmission neurons. These cases represent the deafferented allodynic subtype. In patients of deafferented nonallodynic subtype, pain may result from the activation of the CNS pain transmission neurons (Nurmikko, T. and Bowsher, D., 1990; Fields, H. L. *et al.*, 1998). In a study of 63 PHN patients, 25% of the cases were of irritable nociceptor type, 50% were of deafferentation with allodynia type, and 25% were of deafferentation without allodynia type (Pappagallo, M. *et al.*, 2000).

Pain relief of peripherally acting treatments, that is, topical agents, supports the role of peripheral nociceptors in PHN. Topical lidocaine, when used as a 5% gel under an occlusive dressing (Rowbotham, M. C. *et al.*, 1995) or as 5% patch (Rowbotham, M. C. *et al.*, 1996b; Galer, B. *et al.*, 1999) reduces pain and allodynia in PHN. Because it produces clinically insignificant serum levels, it is thought to relieve pain by reducing ectopic discharges in the affected peripheral afferent fibers by blocking upregulated sodium channels. Topical capsaicin has been studied in two randomized controlled trials (Bernstein, J. E. *et al.*, 1989; Watson, C. P. N. *et al.*, 1993). Capsaicin binds to nociceptors in the skin, causing excitation of neurons and a period of enhanced sensitivity perceived as itching, pricking, or burning, with cutaneous vasodilatation. This is followed by a refractory period with reduced sensitivity to, and after repeated applications, persistent desensitization (Nolano, M. *et al.*, 1999). The efficacy of topical capsaicin appears limited: the decrease of pain intensity was a maximum of 23% in one trial (Watson, C. P. *et al.*, 1993) and 30% in the other (Bernstein, J. E. *et al.*, 1989).

The question of the role of the sympathetic nervous system in PHN is ambiguous. In a double-blind study, the cutaneous infiltration of an adrenergic agonist into PHN skin caused only a modest increase of pain and allodynia severity (Choi, B. and Rowbotham, M. C., 1997). The role of sympathetic blocks in HZ and PHN remains controversial, and direct evidence of a major sympathetic contribution to PHN is nonexistent (Wu, C. L. *et al.*, 2000).

The treatment of HZ aims at minimizing the neural damage with antiviral drugs, maximal pain relief with analgesic drugs, and prevention of PHN. For those who continue to have prolonged pain, the current armamentarium of medical treatments, that is, tricyclic antidepressants, gabapentinoids, opioids, and topical lidocaine should be tested (Dubinsky, R. M. *et al.*, 2004). The possibility of multiple mechanisms in the same patient may explain why response to any single treatment is so often partial and forms a logic base for polytherapy. The detailed information of the efficacy of the treatments on the various components of PHN is lacking.

Glossary

ectopic generator Pathophysiological site of electrical impulse generation in the peripheral nervous system (PNS) or central nervous system (CNS). Ectopic excludes locations of impulse generation in normal, healthy tissue. Examples are nerve-end neuromas and dorsal root ganglia (DRGs) in the event of nerve injury.

electrogenesis The process of electrical impulse generation in nervous system tissue. Electrogenesis usually includes two phases: formation of a generator depolarization (sensory transduction in the case of afferent endings) and encoding of the generator depolarization into an impulse train.

microneurographic recording An electrophysiological technique in which a fine wire microelectrode is inserted transcutaneously into the peripheral nerve, permitting recording of impulse activity in individual nerve fibers. This minimally invasive procedure can be applied to awake humans.

5.06.1 Introduction

Normally, sensation originates in impulse discharge generated at sensory endings in skin, viscera, and other peripheral tissues. When there has been injury to peripheral nerves, neuropathic pain may arise as a result of abnormal impulse discharge generated at ectopic sites. The most common locations of ectopic impulse generation are the site of injury and associated dorsal root ganglia (DRGs). This chapter will touch on the characteristics of ectopic impulse generation (ectopia), the ways in which ectopia contributes to neuropathic pain sensation, and the cellular mechanisms that underlie it.

5.06.2 Nerve Injury and Disease Trigger Ectopia

5.06.2.1 Precipitating Factors

Ectopic impulse generation develops secondary to frank injury of the axon or soma of sensory neurons, or disruption of the myelin sheath that surrounds many axons (dysmyelination and demyelination). Disruption of the Schwann cell sheath that embraces bundles of nonmyelinated axons (Remak bundles) may also be a cause. It is fairly obvious why damage or disease that disrupts the ability of axons to conduct nerve impulses should cause negative sensory abnormalities such as hypoesthesia and numbness. It

is much less obvious why neural pathology causes positive sensory symptoms and signs such as ongoing and evoked paresthesias, dysesthesias, and pain. The link is the emergence of ectopia. If the axotomy happens suddenly, there may be a brief period of injury discharge. In general, however, ectopia results from secondary changes that develop over time (Devor, M., 2006a). The pathophysiological changes that induce ectopia can be precipitated by a wide variety of events including trauma (frequently iatrogenic), nerve entrapment, infection (bacterial or viral), sterile inflammation, metabolic abnormalities, malnutrition, vascular abnormalities, neurotoxins (including many chemotherapeutic agents), radiation, inherited mutations, and autoimmune attack.

5.06.2.2 Spontaneous Ectopic Discharge

A considerable fraction of injured sensory neurons, as many as one-third in some experimental preparations, begin to fire spontaneously in the hours and days following injury. Microneurographic recordings in patients with nerve injury have revealed similar results (Nordin, M. *et al.*, 1984; Devor, M., 2006a). The origin of the activity has been identified as the swollen endbulbs that form in the neuroma just proximal to sites of axonal transection (Fried, K. *et al.*, 1991), outgrowing sprouts, plaques of demyelination, and the cell soma in the DRG. In the event of sudden traumatic neuropathy activity usually begins earliest in myelinated axons (A-fibers), sometimes as soon as 16 h after axotomy, with a preference for muscle over cutaneous afferents. Activity in unmyelinated (C-) fibers tends to appear in earnest later, after a few weeks. Specific parameters vary with the type of injury, source (axon or soma), and strain and species of animal.

Firing pattern is usually tonic-rhythmic (i.e., continuous), bursty, or irregular, with the occasional neuron showing complex, often cyclic variations in firing pattern. The instantaneous firing rate of tonic-rhythmic and bursty activity is typically 15–40 impulses per second (ips), with bursts typically occurring at intervals of between a few per second and one every few seconds (Figure 1). Irregular firing of single spikes occurs at the same relatively slow rate as bursting. The reason for these patterns is now known (Amir, R. *et al.*, 2002b). The basic clock driving ectopia triggers activity at the slow rate. Some cells render only singlet spikes. In others, an iterative process based on postspike depolarizing afterpotentials (DAPs) yields a short rhythmic burst upon each trigger event, resulting in bursty discharge. Tonic autorhythmicity reflects an unending burst, which can occur in cells that generate DAPs but in which the mechanism for ending bursts is relatively ineffective. Interestingly, observations in nerves in which only a part of the axons have been severed show that spontaneous ectopic activity may also develop in neighboring uninjured axons, particularly in C-fibers (Wu, G. *et al.*, 2001; Shim, B. *et al.*, 2005).

5.06.2.3 Ectopic Mechanosensitivity

Gentle percussion over sites of nerve injury, areas of entrapment or neuromas for example, typically evokes an intense stabbing or electric shocklike sensation. This is the Tinel sign. Similar sensations can be evoked by other maneuvers that apply mechanical force to injured

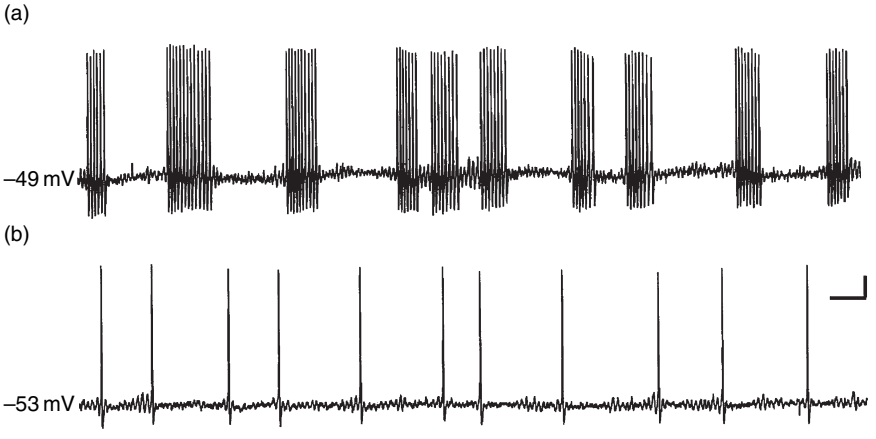

Figure 1 Typical patterns of spike activity generated at ectopic pacemaker sites. (a) Bursty discharge. (b) Irregular singlet firing. Subthreshold oscillations are visible in the baseline traces. Calibrations: 5 mV/100 ms.

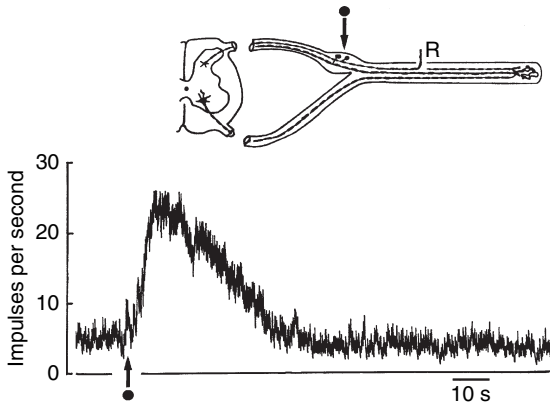

Figure 2 Mechanical afterdischarge. A weak, momentary stimulus to the surface of the DRG triggered a prolonged, self-sustained ectopic discharge burst.

nerves or spinal roots such as straight leg lifting in sciatica (Lasègue's sign), and the signs of Spurling and L'hermitte. Momentary mechanical stimulation of this sort frequently evokes ectopic discharge that outlasts the stimulus itself (afterdischarge), with corresponding aftersensation (Figure 2). This indicates that the underlying process is not just activation of sensitized nociceptors, or signal amplification, but the triggering of autonomous repetitive firing at ectopic pacemaker sites. The nature of this local electrical hyperexcitability is discussed below.

In the event of injuries that leave the nerve in-continuity, such as crush or freeze lesions, there is usually a second Tinel sign that advances with time, marking the farthest position reached by regenerating sprouts. In some conditions (e.g., diabetic neuropathy) paresthesias and pain may occur on tapping anywhere along the course of a nerve. This occurs when there are scattered outgrowing sprouts, demyelination plaques, or mechanosensitive end-bulbs resulting from axonal dying back. Although direct evidence has not yet been sought systematically in humans, it follows logically from studies in animals that pain evoked by deep palpation at tender spots, such as in fibromyalgia, might reflect ectopic mechanosensitivity at locations where small nerve branches cross through fascial planes, under tendons, or are otherwise at risk of being locally pinched.

5.06.2.4 Abnormal Response to Other Stimuli

Ectopic pacemaker sites also develop abnormal sensitivity to other depolarizing stimuli. Notable among these are response to circulating catecholamines and noradrenalin released from nearby (injured) postganglionic sympathetic axons (Devor, M. and Janig, W., 1981). Ectopic adrenosensitivity of sensory neurons yields sympathetic–sensory coupling, a likely substrate of sympathetically maintained chronic pain states. Afferent response to local and circulating inflammatory mediators is a second example of ectopic chemosensitivity. Abnormal discharge may also arise from temperature changes, ischemia, hypoxia, hypoglycemia, and other conditions capable of locally depolarizing afferent neurons at the sites at which they have developed local ectopic pacemaker capability (Devor, M., 2006a). Whereas intact sensory endings may be sensitive to these chemical and physical stimuli, axons in healthy nerve trunks and cell bodies in sensory ganglia are not. The key change in neuropathy is not the presence of excitatory stimuli but rather the ectopic emergence of sensitivity to them.

5.06.3 Ectopic Firing Contributes to Pain Sensation in Several Ways

5.06.3.1 Ongoing Pain, Tender-Points, and Other Sensitivities

The presence of ongoing ectopic discharge under circumstances in which ongoing dysesthesias and pain are present, and their simultaneous exacerbation by the same factors (e.g., mechanical stimulation, sympathetic efferent activity), constitutes *a priori* evidence that the ectopia is the cause of the pain. This conclusion is further supported by the observation that (diagnostic) nerve blocks using local anesthetics reliably obtund pain sensation in cases where the block is placed central to the site of nerve injury (Devor, M., 2006a). An interesting test case often raised as a counterexample is phantom limb pain in amputees. Although this pain is frequently eliminated (transiently) by blocking stump neuromas, there are reports of phantom limb pain persisting despite peripheral nerve block, and this observation has formed the basis for the widely held belief that phantom limb pain reflects abnormal neural activity originating in the cerebral cortex (Melzack, R., 1989; Flor, H. *et al.*, 1995). This conclusion is potentially flawed, however, because it ignores ectopic electrical impulse generation (electrogenesis) in sensory cell somata in the DRG. Amputation stump revision surgery is a common procedure, and is usually done under foramenal or spinal block. Although little published documentation is available (Tessler, M. J. and

Kleiman, S. J., 1994), experienced clinicians insist that these blocks reliably eliminate phantom limb pain for the duration of the pharmacological action of the local anesthetic agent. This would not occur if the pain signal originated supraspinally.

5.06.3.2 Allodynia – Pain Evoked by Stimulation of Residual Uninjured Afferents

Pain in response to light touch of the skin, tactile allodynia, is a common symptom in neuropathy. The simplest explanation is reduced response threshold in nociceptive C-fiber afferents, the classic excitable nociceptor hypothesis. This explanation is probably valid for heat allodynia. However, while neuropathy (and pronociceptive inflammatory mediators) can significantly reduce mechanical thresholds of sensory endings, few fibers that were originally nociceptors come to respond to the very weak tactile stimuli that are typically sufficient to evoke allodynia (Banik, R. K. and Brennan, T. J., 2004; Schlegel, T. *et al.*, 2004; Shim, B. *et al.*, 2005). Moreover, the response to painful touch in allodynic skin is rapid. There is no indication of the long delay between stimulus and response that would be expected from conduction in sensitized C-fibers, although sensitized Aδ nociceptors, if they exist, could contribute.

There is considerable evidence that cutaneous tactile allodynia in neuropathy (and inflammation) is primarily a sensory response to impulse activity in low-threshold mechanosensitive Aβ touch afferents abnormally amplified in the spinal cord (Campbell, J. N. *et al.*, 1988; Torebjork, H. *et al.*, 1992). The altered signal processing responsible for this Aβ pain is believed to result from one or a combination of numerous central nervous system (CNS) changes collectively called central sensitization (Woolf, C. J., 1983; Devor, M., 2006b). Central sensitization, which also amplifies ectopic afferent signals (spontaneous and evoked), is a dynamic process triggered and maintained by ongoing nociceptive input from the periphery. When the maintaining peripheral drive is eliminated, central sensitization fades, along with tactile allodynia. In neuropathy, sustained ectopic discharge can maintain central sensitization indefinitely, and with it Aβ pain and tactile allodynia (Gracely, R. *et al.*, 1992; Koltzenburg, M. *et al.*, 1994). This constitutes a second role of ectopia, in addition to providing a primary pain signal.

In contrast to the skin, it is likely that peripherally sensitized nociceptors play an important role in pain evoked by mechanical stimuli in inflamed viscera and deep somatic tissues such as muscles and joints. Reduced mechanical thresholds, including the recruitment of previously silent C-nociceptors, render the sensory endings of these afferents responsive to the (substantial) forces present during weight bearing, for example, or joint rotation (Schmidt, R., 1996). There is also good evidence for a contribution of central sensitization in deep tissue pain (Banic, B. *et al.*, 2004). Relatively little is known about changes in the response of injured afferent neurons, or the sensory endings of residual noninjured afferents, in the presence of neuropathy affecting nerves that supply deep tissues.

5.06.4 Cellular Mechanisms of Ectopic Impulse Generation

5.06.4.1 Resonance

The emergence of ectopic hyperexcitability in neuropathy is not a simple matter of lowered spike threshold. Rather, it reflects a more fundamental, qualitative change in the injured neuron's electrical characteristics. Most intact sensory neurons are incapable of generating sustained impulse discharge in midnerve or from within sensory ganglia, even in the presence of a strong sustained depolarizing stimulus. They are designed to fire exclusively in response to stimuli applied to the sensory ending in skin, muscle, etc., where the neuronal membrane is specialized for electrogenesis. Alterations in three cellular processes, gene expression, protein trafficking, and channel kinetics (below), actually create repetitive firing capability *de novo* at ectopic locations.

Ectopic repetitive firing capability (pacemaker capability) derives from electrical resonance that emerges in the cell membrane of the injured afferents, and resultant subthreshold oscillations in their normally stable resting potential (Amir, R. *et al.*, 1999; Wu, N. *et al.*, 2001). Subthreshold oscillations drive sustained ectopic discharge. This takes the form of irregular singlet spikes in some cells, and as repetitive bursting in others, depending on the ability of the cell to generate DAPs (Figure 1). Due to subthreshold oscillations, ectopic generator sites become responsive to slow onset and tonic depolarizing stimuli, which previously did not evoke sustained discharge. Some begin to fire spontaneously at rest, in the absence of stimulation. The biophysical processes that lead to membrane resonance, repetitive firing capability, ectopic discharge, and neuropathic pain are slowly coming into focus. Briefly, resonance in neuropathy appears to reflect reciprocation between inward Na^+

current carried by fast-activating, inactivating, and repriming tetrodotoxin (TTX)-sensitive Na^+ channels, and K^+ current passing through one or more voltage-insensitive K^+ leak channels, perhaps of the KCNK K2p family (Abdulla, F. A. and Smith, P. A., 2002; Amir, R. *et al.*, 2002a; Waxman, S. G., 2002). Voltage-sensitive K^+ channels tend to hold resonance in check, and their downregulation after axotomy is probably an important adjunct to ectopia (Kocsis, J. D. and Devor, M., 2000). Other channel types/conductances that might contribute to resonance characteristics of primary sensory neurons include certain Ca^{2+} channels, HCN (the Ih pacemaker channel), KCNQ-type K^+ channels, the β4 subunit-associated resurgent Na^+ current, and a persistent Na^+ conductance (gNaP), but their role, at this stage, is speculative. Many of the first-line analgesic agents used in the treatment of neuropathic pain (McQuay, M. and Moore, A., 1998), including (certain) anticonvulsants, tricyclic antidepressants, systemic local anesthetics, and (certain) antiarrhythmics are thought to act by stabilizing membrane resonance (Catterall, W. A., 1987; Deffois, A. *et al.*, 1996).

5.06.4.2 The Development of Ectopic Pacemaker Capability

The cascade of cellular events that lead to pacemaker capability and ectopic neuronal discharge begins with the injured primary sensory neuron. Our current understanding of the process is as follows. Axonal transection blocks the normal retrograde flow of neurotrophic signaling molecules (glial cell-derived neurotrophic factor (GDNF), nerve growth factor (NGF), and perhaps others) between the periphery and the sensory cell body. This triggers a change in the quantity of various proteins expressed by the cell body and exported by anterograde axoplasmic transport to both peripheral and central axon endings; some are upregulated and others downregulated (Boucher, T. J. and McMahon, S. B., 2001; Costigan, M. *et al.*, 2002; Xiao, H. S *et al.*, 2002). These changes alter the phenotype of the injured neuron, increasing its intrinsic resonance and supporting the emergence of ectopic electrogenesis.

In addition to changes in gene expression in injured sensory neurons, the delivery (trafficking) of transported molecules is disrupted. The most important change of this sort is the accumulation or depletion of molecules of excitability at ectopic generator sites (Figure 3), notably the accumulation of Na^+ channels (Devor, M., *et al.*, 1989; Devor, M., 2006a). Na^+ channels, for example, accumulate in neuroma endbulbs and sprouts, and in areas of demyelination. A third process that contributes to ectopic electrogenesis is altered channel kinetics. It is not ion channel proteins themselves that determine cell excitability but the ionic currents they carry. Increasing mean channel open time, for example, can have much the same effect on excitability as increasing the number of channels present. Proinflammatory cytokines and other mediators associated with neuropathy can affect channel kinetics in this way. For example, cAMP-dependent phosphorylation of Na^+ channel molecules reduces Na^+ current, while dephosphorylation returns it to normal (e.g., Li, M. *et al.*, 1992; Gold, M. S. *et al.*, 1996). Because certain hormones, trophic factors, cytokines, and other inflammatory mediators (notably prostaglandins) can activate protein kinases (PKA, PKC), they are positioned to affect the basic excitability of afferents, and not just to depolarize and excite sensory endings.

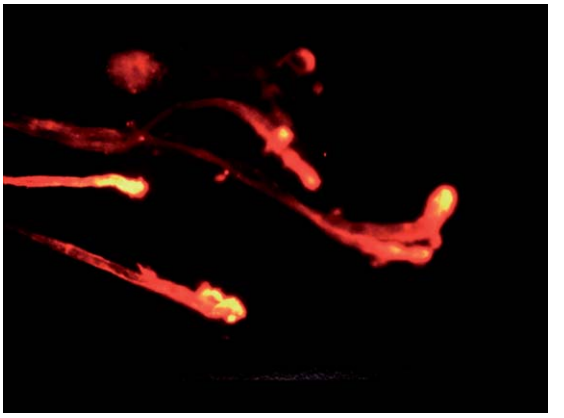

Figure 3 Immunolabeling shows the accumulation of Na^+ channels at the chronic cut end of hyperexcitable injured axons in an experimental nerve-end neuroma (for details see Devor, M. *et al.*, 1989).

5.07.1 How Do Sodium Channels Work?

All sodium channels are single proteins made up of α-subunits that contain four homologous domains and form a voltage-gated sodium-selective aqueous pore (Figure 1). They comprise a family of nine structurally related α-subunits (Table 1). They are more than 75% identical over the amino acid sequences comprising the transmembrane and extracellular domains (Yu, F. H. and Catterall, W. A., 2003). The α-subunits show distinct patterns of expression, and are associated with accessory β-subunits that modify channel properties and interact with cytoskeletal and extracellular matrix proteins. The mechanism of channel gating involves the movement of voltage sensors (shown with positive charges in Figure 1) in response to changes in membrane potential. Lysine or arginine residues are found at intervals of three amino acids to produce a linear array of positive charges in the α-helical S4 transmembrane segments, and the movement of these charged areas of the channel opens the sodium-selective pore, defined by residues within the channel atrium. An intracellular loop lying between transmembrane domains 3 and 4 containing the tripeptide isoleucine phenylalanine methionine (IFM) is subsequently responsible for channel inactivation on a millisecond timescale. Sodium channel subtypes can be pharmacologically distinguished by their susceptibility to block by tetrodotoxin (TTX), a toxin isolated from puffer fish, which binds to the ion selectivity pore of some channels (Hille, B., 2002). Most sodium channels are blocked by nanomolar concentrations of TTX and are defined as TTX-sensitive (TTXs) whilst others are resistant to micromolar TTX and are defined as TTX-resistant (TTXr).

A short sequence found upstream of neuronal sodium channel genes (as well as other neuronal genes) was identified and named neuron-restricted silencing element (NRSE) or repressor element 1(RE-1). Transcription factors that bound to the motif were found to act as inhibitors of gene expression in nonneuronal cells. These proteins were named RE-1 silencing transcription factor (REST) or neuron-restrictive silencer factor (NRSF) and mutational analysis identified a single zinc finger motif in the carboxyl-terminal domain of the factor as essential for repressing sodium channel-derived reporter genes (Kraner, S. D. *et al.*, 1992). The inhibitory activity of the complex can be further modulated by double-stranded RNA molecules that have the same sequence as NRSE/RE-1, and are found in developing neuronal precursors. These regulatory RNA molecules are able to switch the repressor function of the complex to an ac activator role (Kuwabara, T. *et al.*, 2004). In this way, the assumption of a neuronal phenotype seems to depend in part upon regulatory RNAs driving gene expression downstream of NRSE/RE1 motifs. Sodium channels are known to be expressed at the very earliest stages of the appearance of a neuronal phenotype in the mouse. These studies highlight the significance of sodium channel expression in neuronal function throughout development.

The α-subunits of the voltage-gated sodium channel that form the sodium pore are associated with accessory β-subunits that modulate channel properties and interact with cytoskeletal and extracellular

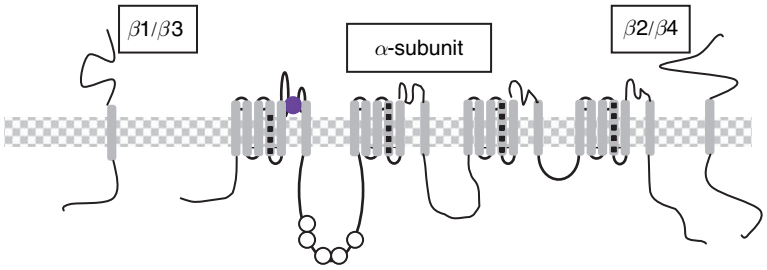

Figure 1 Structure of sodium channels. Voltage-gated sodium channels comprise a single functional α-subunit, which is tethered by associated accessory subunits to subcellular locations determined by both extracellular and intracellular proteins. Phosphorylation sites are shown on intracellular loop 2, and the serine residues in domain 1 that confers tetrodotoxin sensitivity is highlighted.

Table 1 Names and properties of voltage-gated sodium channel α-subunits

Type	*Gene symbol*	*Name*	*Tissue*	*TTX-sensitive*
$Na_V1.1$	SCN1A	Type I	CNS/PNS	+
$Na_V1.2$	SCN2A	Type II	CNS	+
$Na_V1.3$	SCN3A	Type III	CNS	+
$Na_V1.4$	SCN4A	SKM1	Skeletal muscle	+
$Na_V1.5$	SCN5A	SKMII	Heart/CNS	−
$Na_V1.6$	SCN8A	Nach6	CNS/glia	+
$Na_V1.7$	SCN9A	PN1	DRG	+
$Na_V1.8$	SCN10	SNS	DRG	−
$Na_V1.9$	SCN11	NAN	DRG	−

The nomenclature for sodium channel α-subunits, combined with their main site of expression (CNS – central nervous system, PNS – peripheral nervous system) and their sensitivity to block by tetrodotoxin (TTX), is shown.

matrix proteins. β-subunits are single transmembrane domain proteins that contain an extracellular domain that is homologous to the V-set of the immunoglobulin superfamily that includes cell adhesion molecules (Isom, L. L., 2002). The biochemical purification of two proteins, β1 and β2, that associate with α-subunits allowed the properties of these accessory factors to be investigated in heterologous expression systems. Molecular cloning has identified a β1-like member of the family named β3 and β2-like subunit named β4, as well as a splice variant of β1, β1A.

β1 and β1A are structurally homologous in the extracellular immunoglobulin-like loop region. β1A mRNA is expressed during embryonic development, and becomes undetectable after birth, concomitant with the onset of β1 expression. Immunocytochemical analysis of β1A expression revealed selective expression in brain and spinal cord neurons, with high expression in heart and all dorsal root ganglia neurons. Coexpression of $Na_v1.2A$ and β1A-subunits results in a 2.5-fold increase in sodium current density as a result of an increase in the level of functional sodium channels in expressing cells. β1A-expressing cell lines also revealed subtle differences in sodium channel activation and inactivation. β3 most closely related to β1 is the product of a separate gene localized to human chromosome 11q23.3. The expression pattern of β3 differs significantly from β1.

Coexpression of the β-subunits with sodium channel α-subunits in *Xenopus* oocytes or mammalian cell lines accelerates channel activation, and shifts the voltage dependence of inactivation to more negative potentials, indicating that β-subunits are important in the assembly, expression, and functional modulation of the rat brain sodium channel heterotrimeric complex (Isom, L. L., 2002). However, β-subunits do not appear to modulate the biophysical properties of all sodium channel α-subunits. $Na_v1.8$ α-subunits show aberrant properties when expressed in heterologous cells, but coexpression with β1, β1A, or β3 does not recapitulate normal channel behavior. The existence of factors other than accessory β-subunits that can alter inactivation kinetics has also been suggested by studies in which sodium channel α-subunits are expressed in cells lacking endogenous sodium channel β-subunits. Expression of rat cardiac $Na_v1.5$ and rat brain $Na_v1.2$ sodium channels in mammalian cell lines results in sodium channels

with rapid activation and inactivation characteristic of native neuronal sodium channel.

An additional function of β-subunits as cell adhesion molecules has been demonstrated by the ability of β-subunits to mediate homophilic interactions via their extracellular immunoglobulin-like repeats (Isom, L. L., 2002). Interacting β-subunits also recruit the cytoskeletal protein ankyrin-G to the cell surface via an interaction with their cytoplasmic domains, suggesting that these subunits link sodium channel α-subunits indirectly both to the cytoskeleton and to the extracellular matrix proteins, such as tenascin-R. Tenascin-R is an extracellular matrix molecule that is secreted by oligodendrocytes during myelination and that binds F3-contactin. Transfected cells stably expressing β1- or β2-subunits initially recognize and then are repelled from substrates containing tenascin-R. The cysteine-rich amino-terminal domain of tenascin-R appears to be responsible for the repellent effect on β-subunit-expressing cells. Application of the cysteine-rich N-terminal domain of tenascin-R to channels expressed in *Xenopus* oocytes potentiates expressed sodium currents. The binding of neuronal sodium channels to extracellular matrix molecules such as tenascin-R may thus play a role both in functional regulation and in localizing sodium channels in high density at nodes of Ranvier.

β-subunits also interact with the ankyrin-G membrane skeletal protein that is associated with spectrin–actin networks and also binds to integral membrane proteins including the L1 CAM family of cell adhesion molecules. Ankyrin-G is highly concentrated along with the L1CAM family members neurofascin and NrCAM at nodes of Ranvier and axon initial segments. Voltage-gated sodium channels are thus likely to associate in a complex containing neurofascin/NrCAM and ankyrin-G in myelinated neurons.

As well as the accessory subunits that link sodium channels to cytoskeletal and extracellular elements, other proteins are associated with sodium channels. Voltage-gated sodium channels in brain neurons were found to associate with receptor protein tyrosine phosphatase-β (RPTP-β) (Catterall 200. Both the extracellular domain and the intracellular catalytic domain of RPTP-β interact with sodium channels. Sodium channels were found to be tyrosine phosphorylated and dephosphorylation slowed $Na_v1.1$ inactivation, positively shifting voltage dependence and increasing whole-cell sodium current.

Regulation of sodium channels by protein kinases (PK) has already been demonstrated in a number of systems. Protein kinase A (PKA) can decrease or increase sodium currents by phosphorylation at consensus sites in the cytoplasmic domain I–II linker. Effects on membrane trafficking may also be mediated through phosphorylation. In the case of the cardiac channel, activation of PKA causes a slow increase in sodium current in *Xenopus* oocytes. Chloroquine and monensin, both compounds that disrupt plasma membrane recycling, reduce sodium currents. Preincubation with these agents also prevented the PKA-mediated rise in sodium current, indicating that this effect likely resulted from an increased number of channels in the plasma membrane.

There is strong evidence for specialized roles of the various sodium channel isoforms based on human genetic studies as well as the production of knockout mice. A perinatal lethal phenotype occurs in the $Na_v1.2$ sodium channel mouse knockout, which shows severe hypoxia as a result of brain stem apoptosis. $Na_v1.8$ channel knockouts have selective deficiencies in pain pathways (Akopian, A. N. *et al.*, 1999). Nax, a non-voltage-gated sodium channel homologue has been shown to play an important role in salt homeostasis, whilst loss of $Na_v1.6$ in the natural *med* mutant has been shown to lead to ataxia, dystonia, and paralysis. The deletion of accessory β-subunits, already known to play an important role in regulating functional channel expression and tethering α-subunits to specific subcellular locations, leads to a complex phenotype resulting in seizures and epileptogenic activity.

Naturally occurring mutations in both sodium channel α- and β-subunits have been implicated in various inherited disorders, many of which have been characterized in muscle sodium channel isoforms. Brugada syndrome, characterized by ventricular fibrillation, heart failure, and sudden death, is associated with mutations in the cardiac sodium channel $Na_v1.5$. Hyperkalemic periodic paralysis is associated with mutations in the skeletal muscle channel $Na_v1.4$. However, there is also evidence of a role for neuronal sodium channels and β-subunits in a variety of pathologies, including epilepsy, autism, and pain perception. Generalized epilepsy with febrile seizures (GEFS) is associated with mutations in either the β1-subunit (type I) or the α-subunit $Na_v1.1$ (type II). Some forms of autism associate with mutations in SCN1-3A sodium channel genes. The peripheral neuron-associated sodium channel $Na_v1.7$ encoded by gene SCN9A has been shown to be the site of mutations that lead to the chronic familial pain disorder primary erythermalgia (Yang, Y. *et al.*, 2004). This dominant condition is characterized by burning

in the extremities, pain evoked by standing and a generalized inflammatory phenotype. Interestingly, systemic treatment with the sodium channel blockers lidocaine or mexiletine leads to dramatic improvements in the symptoms associated with this disease.

Neuronal excitability depends to a considerable extent on sodium channel trafficking, distribution and density, as well as the intrinsic properties of the channels themselves in terms of thresholds of activation and repriming characteristics. The repertoire of sodium channels expressed by sensory neurons and the alterations that occur in pain states are now well documented (Waxman, *et al.*, 2002, Wood, J. N. *et al.*, 2004). Unmyelinated C-fiber-associated dorsal root ganglion (DRG) neurons are usually nociceptive whilst thinly myelinated Aδ-fibers also mediate fast pain, and a subset of myelinated Aβ-fibers are also nociceptive. TTXr sodium channels are present on C-fibers and seem to play a significant role in nociception (Akopian, A. N. *et al.*, 1999).

5.07.2 Sodium Channels and Pain Pathways

Acute, inflammatory, and neuropathic pain can all be attenuated or abolished by local treatment with sodium channel blockers such as lidocaine. The peripheral input that drives pain perception thus depends on the presence of functional voltage-gated sodium channels. Remarkably, two voltage-gated sodium channel genes ($Na_v1.8$ and $Na_v1.9$) are expressed selectively in damage-sensing peripheral neurons, whilst a third channel ($Na_v1.7$) is found predominantly in sensory and sympathetic neurons. An embryonic channel ($Na_v1.3$) is also upregulated in damaged peripheral nerves and associated with increased electrical excitability in neuropathic pain states. A combination of antisense and knockout studies support a specialized role for these sodium channels in pain pathways.

Small-diameter sensory neurons express a variety of sodium channel transcripts as well as a repertoire of electrophysiological and pharmacologically distinct type of sodium currents. Persistent sodium channels that are resistant to TTX are probably encoded for by $Na_v1.9$ channels, whilst the major transient TTXr channel isotype present predominantly in nociceptors is $Na_v1.8$. TTXs currents are encoded by a number of genes including $Na_v1.1$, $Na_v1.7$, and $Na_v1.6$. The current–voltage relationship of these different sorts of sodium channels found in DRG sensory neurons is shown in Figure 2. The persistent current activates at voltages close to the resting potential and is likely to play a role in setting thresholds of activation.

Evidence that altered sodium channel activity in peripheral neurons is associated with the development of inflammatory and neuropathic pain is strong. Altered patterns of sodium channel transcripts as well as changes in posttranslational modifications have been observed. Neuropathic pain that results from direct damage to peripheral nerves is the most problematic condition in terms of analgesic therapy. The pain evoked by these conditions seems to result initially from enhanced neuronal excitability that can be blocked by low-dose TTX.

5.07.3 $Na_v1.3$ and Neuropathic Pain

$Na_v1.3$ is widely expressed in the adult human central nervous system but is normally present at low levels in adult peripheral nervous system. Axotomy or other forms of nerve damage lead to the reexpression of $Na_v1.3$ and the associated $\beta3$-subunit in sensory neurons, but not in primary motor neurons (Waxman, S. G. *et al.*, 1994). This event can be reversed *in vitro* and *in vivo* by treatment with high levels of exogenous glial cell-derived neurotrophic factor (GDNF). $Na_v1.3$ is known to recover (reprime) rapidly from inactivation (Cummins *et al.*, 2001). Axotomy has been shown to induce the expression of rapidly repriming TTXs sodium channels in damaged neurons, and this event can also be reversed by the combined actions of GDNF and nerve growth factor (NGF). Concomitant with the reversal of $Na_v1.3$ expression by GDNF, ectopic action potential generation is diminished and thermal and mechanical pain-related behavior in a rat chronic constriction injury model is reversed. Moreover, $Na_v1.3$ is upregulated in dorsal horn neurons following experimental spinal cord injury and this upregulation is associated with hyperexcitability of these nociceptive neurons and pain; antisense knockdown of $Na_v1.3$ (and probably other sodium channels) attenuates the dorsal horn neuron hyperexcitability and the pain behaviors in spinal cord-injured animals (Hains, B. C. *et al.*, 2003). It therefore seems likely that $Na_v1.3$ reexpression may play a role in increasing neuronal excitability that contributes to neuropathic pain after nerve and spinal cord injury.

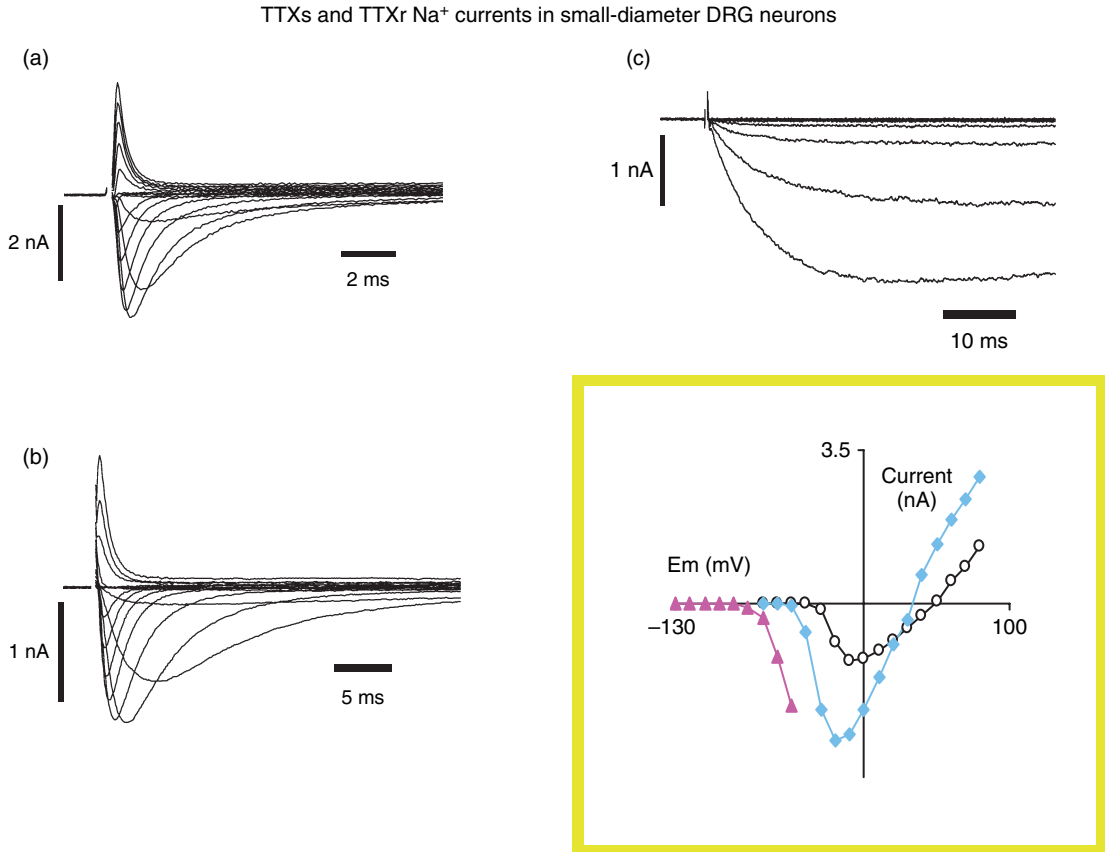

Figure 2 (a) TTX-sensitive (b) -resistant, and (c) persistent currents are shown. Note the different timescales for inactivation of the currents. The voltage at which the different types of channels activate is shown in panel 4 (red channel (c), blue channel (a), and black channel (b)). Although those channels that activate at the most negative potentials might seem to render other channels redundant, the ability to recover from inactivation is also an important determinant of neuronal excitability.

5.07.4 $Na_v1.7$ and Inflammation

$Na_v1.7$ encodes a TTXs channel found predominantly in peripheral sensory and sympathetic neurons. Interestingly, this channel is located at the terminal of sensory neurons, and is regulated in its expression by inflammatory mediators such as NGF, probably through mechanisms that involve the control of trafficking. The fact that a chronic inflammatory dominant human disease, primary erythermalgia, maps to this gene SCN10A suggests that this channel may have an important role in inflammatory pain (Yang, Y. *et al.*, 2004). Tissue-specific deletion in mouse nociceptors shows that $Na_v1.7$ plays a major role in inflammatory pain (Nassar, M. A. *et al.*, 2004). Low-dose lidocaine both inhibits the pain associated with primary erythermalgia and unmasks the phenotype of the $Na_v1.8$ null, further supporting a role for $Na_v1.7$ in inflammatory pain. $Na_v1.7$ mRNA contributes to an increase in TTXs sodium current in caraggeenan-inflamed rats, further implying a role in altering inflammatory pain thresholds. Recently humans with a loss of functional $Na_v1.7$ have been found to be completely pain free (Cox, J. J. *et al.*, 2006). Not surprisingly, this has stimulated major interest in developing an $Na_v1.7$-specific channel blocker.

5.07.5 $Na_v1.8$ and Nociception

$Na_v1.8$ is a TTXr sensory neuron-specific channel mainly expressed in nociceptive neurons. This channel contributes much of the sodium current underlying the depolarizing phase of the action potential in cells in which it is present and knockout mice lose all the inactivating TTXr sodium channel activity in DRG neurons (Akopian, A. N. *et al.*, 1999).

$Na_v1.8$ thus underlies the inactivating TTXr sodium currents that have been found to play a critical role in many aspects of nociceptor function. Functional expression of TTXr currents encoded by this channel is regulated by inflammatory mediators, including NGF. Both antisense and knockout studies support a role for the channel in contributing to inflammatory pain, as PGE_2-induced hyperalgesia is inhibited by antisense oligonucleotides. Antisense studies have also suggested a role for this protein in the development of neuropathic pain (Lai, J. *et al.*, 2002). A late-onset deficit in ectopic action propagation has been described in the $Na_v1.8$-null mutant mouse together with deficits in mechanohypersensitivity. A redistribution of immunoreactive $Na_v1.8$-like material has also been described in animal models of neuropathic pain, further supporting the lobby for $Na_v1.8$ as a key molecule in the pathogenesis of neuropathic pain. However, neuropathic pain behavior at early time points seems to be normal in the $Na_v1.8$-null mutant mouse.

Inflammatory mediators are known to alter the level of TTXr channel expression, and shift their threshold of activation to more negative potentials through the activation of PKA. Prostaglandin E_2, adenosine, and serotonin all increased the magnitude of $Na_v1.8$-mediated currents, shifted its conductance–voltage relation in a hyperpolarizing direction, and increased the rates of activation and inactivation of sodium channels in small-diameter sensory neurons in culture. These phenomena can be replicated *in vitro* with heterologously expressed $Na_v1.8$ channels, implicating this TTXr channel in setting peripheral pain thresholds. In support of a role for the $Na_v1.8$ channel in pain pathways, an $Na_v1.8$-null mutant shows deficits in inflammatory pain processing, in contrast to its responses to neuropathic damage (Akopian, A. N. *et al.*, 1999).

This channel also appears to have an important role in visceral pain. TTXr sodium currents were present in every colonic DRG neuron studied (Gold, *et al.*, 2002). Modulation of TTXr I(Na) in colonic afferents may be an underlying mechanism of hyperalgesia and pain associated with inflammation of the colon. Consistent with this, the $Na_v1.8$-null mutant has deficits in visceral pain and referred hyperalgesia.

Several strands of evidence also support a role for $Na_v1.9$ as an important contributor to the control of excitability in nociceptive afferents. The gene is expressed predominantly in neurons functionally defined as nociceptors. However, the phenotype of a mouse $Na_v1.9$ knockout is essentially normal.

5.07.6 The Diversity of Sodium Channel Subtypes

Given the fairly similar properties of voltage-gated sodium channels why are there so many different types of α-subunits present in nociceptive sensory neurons? A number of explanations are possible:

Firstly, the trafficking in sensory neurons of different sodium channels to distinct cellular locations (terminals, nodes of Ranvier, etc.) and the regulation of this process may provide a number of options to control neuronal excitability in different physiological contexts. Thus trafficking of $Na_v1.8$ into the cell membrane through its interaction with p11, which is massively upregulated by NGF, could play an important role in inflammatory pain – other channels do not show this behavior. It is important to remember that there are no external cues such as nodes of Ranvier to define the topological organization of sodium channels in C-fibers – the relatively even distribution of sodium channels to promote electrical propagation along the length of a very long axon is a process that is not understood, and altered channel density particularly at C-fiber terminals can have important effects on excitability. The two sodium channels that are uniquely associated with C-fibers may be involved in these processes.

Secondly, different structural features of the channels means that their response to posttranslational modification by enzymes such as PK is quite distinct. Phosphorylation on intracellular serines in $Na_v1.8$ increases peak current density, whilst in other channels present in DRG neurons, for example $Na_v1.7$, peak current diminishes. Primary sequence also determines the repriming characteristics of the different channels as well as their threshold of activation, which are crucial determinants of peripheral pain thresholds.

Thirdly, the topological relationship between different sodium channels and channels involved in sensing noxious stimuli may also play a role in setting thresholds of activation and thus pain thresholds. As noxious mechanosensation but not heat sensing is deficient in $Na_v1.8$-null mutant mice, we may argue that this channel is closely apposed to potential mechanosensors through a sequence-specific interaction with a macromolecular complex, and local depolarizations cause this channel to activate first to generate action potentials. Heat sensors may be linked

with other sodium channel subtypes. If true, this would suggest that molecules that disrupt specialized nociceptive complexes at the terminals of sensory neurons may have a useful analgesic effect. There is already evidence that disruption of the cytoskeleton has antihyperalgesic effects.

5.07.6.1 Selective Sodium Channel Blockers as Drugs

Tetrodotoxin has proved invaluable in discriminating between two classes of sodium channels. The $Na_v1.5$ channel, as well as the peripheral neuron-specific channel $Na_v1.8$, is a subfamily of TTXr sodium channels, including the evolutionarily earliest sodium channel $Na_v1.9$. However, little progress has been made in developing specific subtype selective channel blockers. Conotoxins provide a possible route to this goal. The venom from marine predatory cone shell snails (*Conus*) contains a complex cocktail of neurotoxic disulfide-rich peptides, termed conotoxins. Conotoxins produce their toxic effects via the targeted modulation of specific ion channels, and there is some evidence that they target specific sodium channels.

Sodium channel subtypes are thus differentially regulated in different pain states. New subtype selective blockers should therefore prove useful as both research tools and potential analgesic drugs. The presence of DRG-specific sodium channel isoforms presents an exciting opportunity to develop new classes of analgesic drugs that may have quite novel properties from present-day analgesics with utility in some conditions of intractable or chronic pain.

Glossary

AMH A-fiber mechanoheat-sensitive nociceptor responsive to mechanical and heat stimuli.

central sensitization An enhanced neural response that occurs in the central nervous system (CNS).

CMH C-fiber mechanoheat-sensitive nociceptor responsive to mechanical and heat stimuli.

fatigue Decrement in response to repeated stimuli.

hyperalgesia Enhanced stimulus-evoked pain.

MIA Mechanically insensitive afferent.

MSA Mechanically sensitive afferent.

nociceptor Neuron responsive to noxious or injurious stimuli.

primary hyperalgesia Hyperalgesia that develops at the site of injury. Mechanical and thermal hyperalgesia are present at the zone of primary hyperalgesia following a cutaneous injury.

receptive field Area over which neuron is responsive to mechanical, thermal, chemical, or electrical stimulation.

secondary hyperalgesia Hyperalgesia that develops in an uninjured tissue surrounding a site of injury. Only mechanical hyperalgesia is present at the zone of secondary hyperalgesia.

sensitization Enhanced neural response.

5.08.1 Introduction

A vital function of the sensory nervous system is to signal the threat or occurrence of tissue injury. A specialized class of afferents performs this function. These afferents respond preferentially to noxious or injurious stimuli and are called nociceptors. Nociceptors are found in virtually every organ (except the brain), and activity in nociceptive afferents is thought to lead to the percept of pain. In this chapter, we will focus on nociceptors innervating skin. Nociceptors from other somatic tissues have similar properties.

The skin contains a number of distinct sensory receptors that respond selectively to different types of innocuous stimuli and encode different aspects of the sensory experience. For example, several types of low-threshold mechanoreceptors signal different aspects of touch sensation. Receptors that are exquisitely sensitive to gentle warming or gentle cooling are responsible for the percepts of warmth and cooling, respectively.

Nociceptors are distinguished from these innocuous receptors by their relatively high threshold for activation. Unlike innocuous receptors, nociceptors often respond to more than one energy form – that is, they are polymodal. Nociceptors are often subclassified based on the conduction velocity of their parent axon. C-fiber nociceptors are associated with unmyelinated fibers and have conduction velocities less than $2\ m\ s^{-1}$. A-fiber nociceptors are associated with myelinated fibers and have conduction velocities greater than $2\ m\ s^{-1}$.

We will first consider the properties of nociceptors from uninjured skin and how their response is related to sensations of acute pain. We will then consider the effects of skin injury on the response of nociceptors and how this is related to enhanced pain sensitivity called hyperalgesia. Where possible, electrophysiological responses to noxious stimuli will be compared to psychophysical measures of pain.

5.08.2 Nociceptors in Uninjured Skin

In experimental studies of nociceptors, the first task is to identify where on the skin the afferent is responsive. This area is called the receptive field. The receptive field is often located based on its response to mechanical stimuli (e.g., gentle pinching), and then the border is mapped with flexible small-diameter cylindrical probes that exert a relatively constant force when they bend (called von Frey probes). Quantitative stimuli of different energy modalities are then applied to this mechanical receptive field. In early studies, the response of nociceptors to heat and mechanical stimuli was tested leading to the nomenclature of C-fiber (CMH) or A-fiber mechanoheat nociceptors (AMH) corresponding to C-fiber or A-fiber nociceptors responsive to heat and mechanical stimuli. Most of these nociceptors also respond to chemical and/or cold stimuli and therefore are polymodal.

Nociceptors that respond to mechanical stimuli are also called mechanically sensitive nociceptive afferents (MSAs). Recently, it has become apparent that afferents exist that either are insensitive to mechanical stimuli or have extremely high mechanical thresholds; these afferents are called mechanically insensitive afferents (MIAs) or silent nociceptors. These afferents were missed in earlier studies of nociceptors that relied on mechanical techniques to search for the receptive field. MIAs have been identified in many different tissues including skin, cornea, knee joint, and viscera. In the skin, electrocutaneous stimulation can be used to search for the receptive field of MIAs (see Box 1). As will become apparent below, cutaneous MIAs differ from MSAs not only in their response to mechanical stimuli but also in their response to other stimulus modalities.

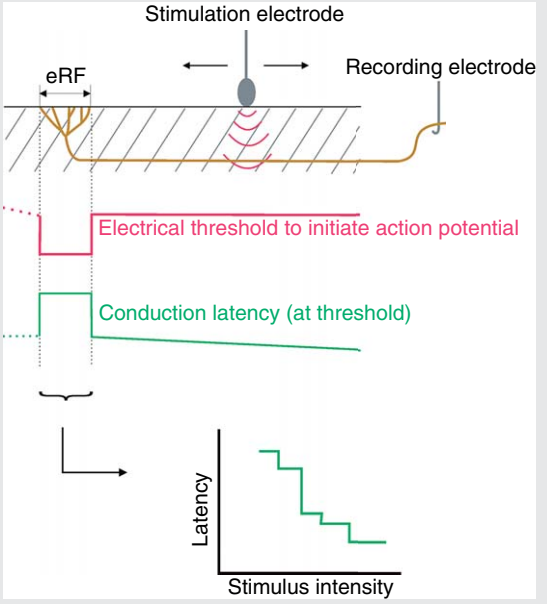
5.08.2.1 C-Fiber Nociceptors

The response of a typical CMH to a stepped increase in temperature in the receptive field is shown in Figure 1. For stimuli applied to the skin, there are five processes that occur to achieve this heat response. First, the heat stimulus needs to be absorbed by the skin. Second, the energy must be transmitted to the receptor terminal that sits below the skin surface. Third, the energy must be converted (or transduced) into a change in membrane potential at the terminal of the nociceptor. Molecular mechanisms of heat transduction are described in Chapter Molecular Biology of the Nociceptor/Transduction. Fourth, the increase in membrane potential must be sufficient to generate an action potential. Finally, the action potential must propagate orthodromically to the central nervous system (CNS) (and to the recording electrode).

Thermal modeling studies combined with electrophysiological recordings indicate that the heat threshold of CMHs in monkeys depends on the temperature at the depth of the receptor terminal and not on the rate of temperature change (Tillman, D. B. *et al.*, 1995). Based on this analysis, the majority of CMHs have heat thresholds between 39 and 41 °C. However, the depth of the heat-responsive terminal

Box 1 Mapping mechanically insensitive afferents

Mechanically insensitive afferents (MIAs) either are completely unresponsive to mechanical stimuli or have such a high threshold for activation that they cannot be activated by light pinch stimuli applied to the skin. Mechanical stimuli are inadequate to locate the cutaneous receptive field of these afferents. Furthermore, repetitive noxious mechanical and heat stimuli could sensitize the nociceptive endings over the course of an electrophysiological experiment. Also, the use of mechanical and thermal stimuli bias the study toward those afferents that are responsive to these stimuli. Because of these reasons, a different search strategy has been developed that allows the receptive fields of afferents, including MIAs, to be localized in an unbiased manner. Instead of using natural stimuli, an electrical stimulus is applied to the skin (see adjacent figure).



A saline-soaked cotton swap is used as a monopolar cathotic search electrode to locate the receptive field. Electrical stimuli are applied through the cotton swap at the skin over the presumed path of the cutaneous nerve from which the recordings are obtained. In response to the electrical stimulus, the afferent nerve fiber is excited and an action potential is generated and conducted to the recording electrode. The latency depends on the conduction velocity of the nerve fiber and the conduction distance. When the stimulation electrode is moved further distally along the peripheral nerve, the conduction latency (green line) of the unit increases due to the increase in conduction length. By moving the electrode further distally, the path of the unit can be traced peripherally toward its receptive field. The receptive field has been located when three phenomena occur. First, the threshold electrical stimulus intensity (pink line) that is needed to excite the afferent transcutaneously drops to its minimum. This drop is most likely due to the fact that the afferent nerve fiber ends in peripheral terminals that are located in the superficial layers of the skin. Therefore, the distance between the stimulation electrode and the nerve endings is minimized. Second, at stimulation threshold, the conduction latency of the action potential increases to its maximum, since the action potential is generated at the most distal part of the axon, that is, its peripheral ending. This latency increase is not continuous but a step increase. Third, within the electrical receptive field (eRF), the latency of the action potential decreases in discrete steps as the stimulus intensity increases. These sudden latency jumps are thought to be due to a switch of the action potential initiation site, for example, from a distal site of the axon (like the most distal ending) to a more proximal site (like a branch point) when the stimulus intensity is increased. Skin sites at which the conduction latency decreases in discrete steps with increasing stimulus intensity belong to the eRF of the unit under study. The described technique can therefore be used to locate the peripheral receptive field and to delineate its borders.

varies widely (from 20 to 570 µm below the skin surface). Since the tissue at the depth of the receptor heats more slowly than the skin surface due to thermal inertia, the heat threshold as measured by the surface temperature of the skin can vary greatly.

The heat response of CMHs increases monotonically with skin temperature above threshold. This suprathreshold response varies directly with the rate of temperature change at the receptor – slow temperature changes give lower instantaneous discharge frequencies than fast temperature changes.

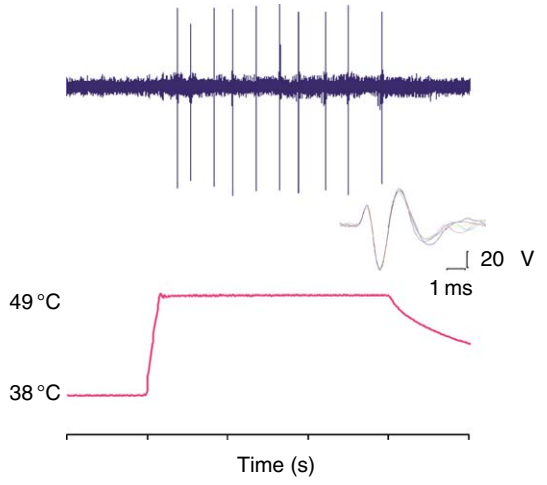


Figure 1 Response of a typical C-fiber mechanoheat-sensitive afferent (CMH) to a heat stimulus. A laser thermal stimulator was used to deliver a constant temperature stimulus (from a 38 °C baseline to 49 °C for 3 s) to the receptive field of a CMH on the hairy skin of the hand of an anesthetized monkey. The large action potential waveform corresponds to a CMH that responded with 10 action potentials to this stimulus. Inset: High-resolution recording of action potential waveforms.

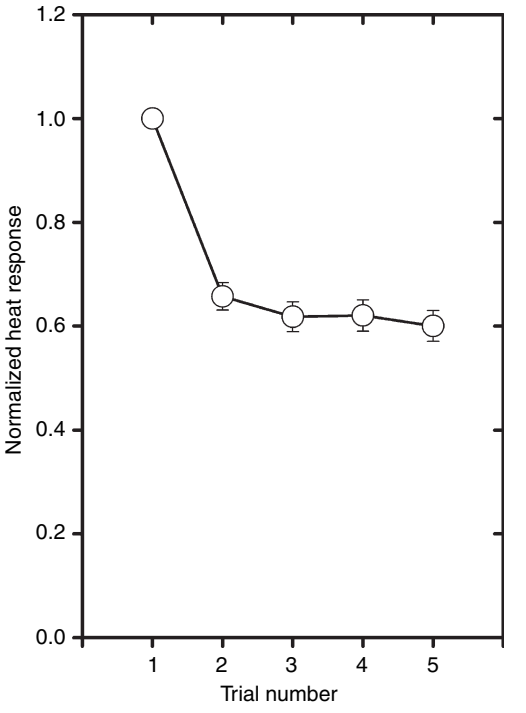

Figure 2 C-fiber mechanoheat-sensitive afferents (CMHs) exhibit fatigue to repeated heat stimuli. Identical heat stimuli were presented every 60 s to the receptive field of CMHs recorded from the anesthetized monkey. The response decreased significantly to the second stimulus and reached a plateau after several stimuli. Data were normalized by dividing by the response to the first stimulus. Adapted from Peng, Y. B., Ringkamp, M., Meyer, R. A., and Campbell, J. 2003. Fatigue and paradoxical enhancement of heat response in C-fiber nociceptors from cross-modal excitation. J. Neurosci. 23, 4766–4774, copyright 2003 by the society for Neuroscience, with permission.

The heat response of CMHs is strongly influenced by stimulus history. For example, when identical heat stimuli are repeated every 60 s, the response to the second stimulus is about 66% of the response to the first (Figure 2). This decrement in response is called fatigue. The amount of fatigue is inversely related to the interstimulus interval (i.e., shorter intervals lead to more fatigue) and directly related to the magnitude of the preceding stimulus (i.e., the larger the preceding stimulus, the greater the fatigue). As a result of fatigue, the shape of the stimulus–response function can also vary with stimulus history. Fatigue can also greatly influence threshold measurements. Complete recovery from fatigue takes more than 10 min.

A decrease in the heat response can also be produced by mechanical stimulation of the receptive field or electrical stimulation of the parent axon (Peng, Y. B. *et al.*, 2003). Thus, fatigue to one stimulus modality can be produced by a stimulus of a different modality. Interestingly, recovery from cross-modal fatigue is much faster than recovery from fatigue produced by the same stimulus modality. This suggests that cross-modal fatigue does not effect the stimulus transduction apparatus in the same way as unimodal fatigue.

In contrast to fatigue, which leads to a decreased response, the response of nociceptors can also be enhanced, for example, by tissue injury. This sensitization may account for aspects of hyperalgesia and is discussed in more detail later in this chapter.

CMHs do not respond to mechanical stimulation with blunt objects but respond well to application of sharp objects. Their mean mechanical threshold to von Frey probes is 2.2 bars. The receptive field size is around 20 mm^2 in monkeys but can be much larger in humans. The receptive field typically consists of multiple punctate regions of high mechanical sensitivity surrounded by areas of lesser sensitivity. Presumably these hot spots correspond to the locations of the receptor terminals.

For cylindrical probes, the response at a given force increases as the size of the probe decreases (Garell, P. C. *et al.*, 1996). This relationship scales inversely with a linear dimension of the probe (i.e.,

probe circumference) not probe area. Thus, the adequate stimulus for activating nociceptors appears to be related to force per unit length, and activation of the receptor terminals appears to occur at the edge of the probe where the strain is the greatest.

C-fiber MIAs are by definition insensitive to mechanical stimuli but are more responsive to chemical stimuli than CMHs and may be considered as chemosensors. For example, microneurographic recordings in human subjects (see Box 2) have shown that capsaicin (the active ingredient in hot peppers) evokes a vigorous response in C-fiber MIAs. Histamine also vigorously activates a subpopulation of C-MIAs. In contrast, histamine and capsaicin evoke weak responses in CMHs. Interestingly, MIAs can develop a response to mechanical stimuli after skin injury (discussed in more detail below).

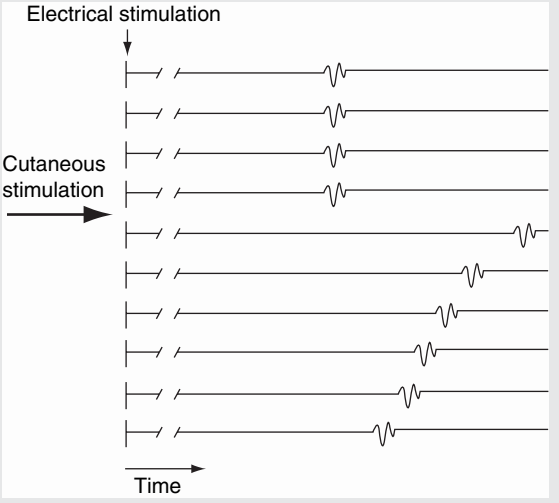
C-MIAs also differ from C-MSAs with regard to their conductive properties. Most unmyelinated fibers exhibit a slowing of conduction with repetitive electrical stimulation that is called activity-dependent slowing. C-MIAs show significantly more slowing than C-MSAs (Weidner, C. *et al.*, 1999). One possible explanation for this finding is that the relative distribution of ion channels involved with conduction is different in these two classes of afferents.

C-fiber afferents with extremely low thresholds to mechanical stimuli have been identified in the hairy skin of rodents, monkeys, and humans (Nordin, M., 1990). These afferents are responsive to light stroking of the skin but not to heat. They are thought to be involved in the sensation of pleasant touch and therefore may play a role in affiliative behavior.

C-fiber afferents with extremely low thresholds to heat are prevalent in all species. These afferents do not respond to mechanical stimuli but have ongoing activity at room temperature and respond to gentle warming of the skin (Darian-Smith, I. *et al.*, 1979).

Box 2 Marking technique

The marking technique is used in recordings that are hampered by a small signal-to-noise ratio that makes the identification of an action potential based on its waveform impractical. The marking technique is commonly used in human microneurography experiments, in which the signal-to-noise ratio is usually small. To use the marking technique, the primary afferent is electrically activated at a constant frequency (e.g., one stimulus every 4 s) through a pair of needle electrodes that are inserted intradermally close to the receptive field of the unit. In response to the ongoing low-frequency electrical stimulation, an action potential can be recorded at the recording electrode at a constant, fixed conduction latency (see the following figure).



If the unit is also activated by a cutaneous (mechanical, thermal, and chemical) stimulus (see arrow), the conduction latency of the following electrically induced action potential will increase. This increase in conduction latency marks the unit as being activated by the stimulus applied to the receptive field. With ongoing electrical stimulation, the conduction latency slowly recovers to the original latency. Marking obviously indicates slowing of conduction along the course of the axon and is thought to be due to the additional action potentials that were initiated by the mechanical (or heat or chemical) stimulus and were conducted along the axon. Due to these additional action potentials, more sodium channels along the axonal membrane will be in an inactivated state when the next action potential induced by the ongoing electrical stimulation is generated and conducted. As a consequence of this inactivation, the conduction velocity for this action potential is decreased, leading to an increase in conduction latency.

Table 1 Properties of type I and type II A-fiber nociceptors

Property	*Type I*	*Type II*
Heat threshold (short-duration stimuli)	High	Low
Heat threshold (long-duration stimuli)	Low	Low
Response to heat	Slow onset, slowly increasing	Fast onset, rapidly adapting
Mechanical threshold	Low (mostly MSAs)	High (mostly MIAs)
Conduction velocity	Aδ and Aß fibers	Aδ fibers
Sensitization after heat injury	Yes	No
Location	Hairy and glabrous skin	Hairy skin

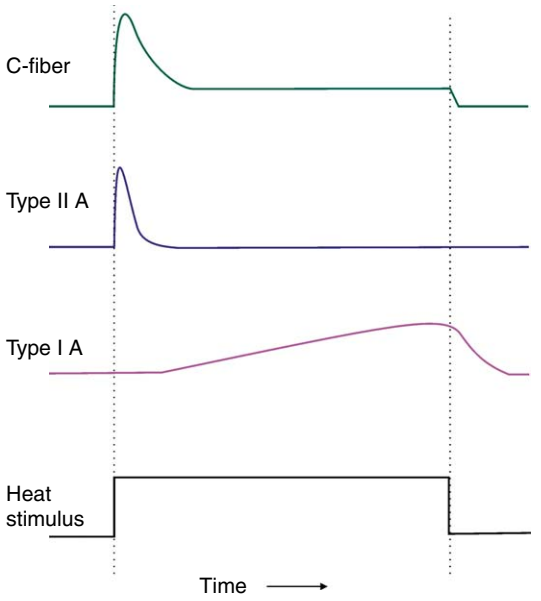


Figure 3 Response of nociceptors to a long-duration intense heat stimulus. The response of C-fiber nociceptors is quick and slowly adapts. The response of type II A-fibers is also quick but quickly adapts. The response of type I A-fibers is slow and builds during the stimulus.

The ongoing activity is suppressed by cooling. These afferents are thought to serve the percept of warmth and are often referred to as warm fibers.

5.08.2.2 A-Fiber Nociceptors

Two distinct types of heat-sensitive A-fiber nociceptors have been described (Table 1) (Treede, R.-D. *et al.*, 1998). Type I fibers are responsive to mechanical and chemical stimuli but have relatively high heat thresholds when short-duration stimuli are used. For this reason, they have also been called high-threshold mechanoreceptors (HTMs). However, most type I A-fibers respond to long-duration heat stimuli (Figure 3), and their thresholds to long-duration heat stimuli are low. In addition, they develop a response to short-duration heat stimuli after injury. Heat transduction in type I afferents is thought to be subserved by the transient receptor potential channel V2 (TRPV2) ion channel. The mechanical threshold and receptive field size for type I AMHs are comparable to those of CMHs. The mean conduction velocity of type I fibers is around 25 m s^{-1} with some fibers having conduction velocities as high as 55 m s^{-1}. Thus, their conduction velocity overlaps the traditional Aß and Aδ myelinated fiber range. Type I AMHs are found in both hairy and glabrous skin.

Type II A-fiber nociceptors are characterized by a fast response to heat stimuli that quickly adapts (Figure 3). Their heat thresholds to short-duration stimuli are much lower than those of type I AMHs. Most type II fibers have very high mechanical thresholds or do not respond to mechanical stimuli and therefore are MIAs. Their mean conduction velocity (15 m s^{-1}) places them within the Aδ myelinated fiber range. In monkeys, they are only found in hairy skin.

Similar to CMHs, A-fiber nociceptors do not respond to mechanical stimulation with blunt object but respond well to sharp objects. The response to mechanical stimuli varies with position in the receptive field. When a 100 µm wide blade is systematically moved to different positions within the receptive field, highly reproducible receptive field response maps can be obtained that contain multiple peaks and valleys (Slugg, R. M. *et al.*, 2004). As the force increases, the response and width of the peaks increase, the response in the valleys increases, and new peaks emerge (Figure 4(a)). Although the response increases with force in most positions in the receptive field, there are positions where the response reaches a plateau at higher forces (Figure 4(b)). The averaged response across the receptive field provides an estimate for the response in the population of nociceptors that innervates a particular location (Figure 4(c)). The population response function for A- and C-fiber nociceptors

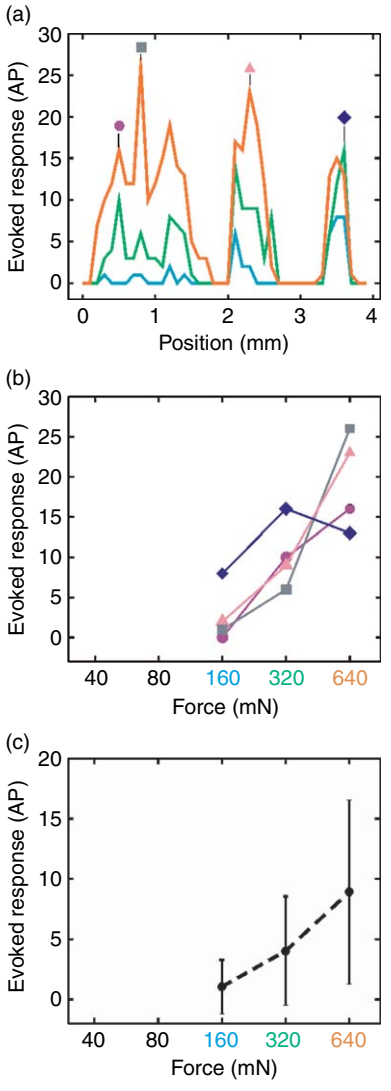

Figure 4 Response of a type I A-fiber nociceptor to a blade stimulus. (a) Maps of response as a function of position and force. A 100 μm wide blade was systematically applied to every position across the receptive field. The response shows peaks and valleys that grow in height and width as the stimulus strength increased (forces: 160, 320, and 640 mN). (b) Stimulus–response function varied with position in the receptive field. In most positions, the response increased monotonically with force, but in one position shown the response reached a plateau at the higher forces. (Symbols in (a) indicate the positions plotted.) (c) The average response across the receptive field is plotted. This provides an estimate of how the population of nociceptors that innervate a single spot on the skin would respond to the stimulus. Adapted from Slugg, R. M., Campbell, J. N., and Meyer, R. A. 2004. The population response of A- and C-fiber nociceptors in monkey ncodes high-intensity mechanical stimuli. J. Neurosci. 24, 4649–4656, copyright 2004 by the Society for Neuroscience, with permission.

increases monotonically with force. The main differences between A- and C-fiber nociceptors are (1) A-fibers in general exhibit a larger response than C-fibers, (2) the population response of A-fibers quadruples with every doubling of force, whereas the response of C-fibers doubles with every doubling of force, and (3) the A-fibers exhibit a better differential response with respect to different probe sizes and forces (Garell, P. C. *et al.*, 1996; Slugg, R. M. *et al.*, 2000).

Aδ-fiber afferents with ongoing activity are present in monkeys and humans. The neural activity in these afferents increases with gentle cooling and decreases with gentle warming (Darian-Smith, I. *et al.*, 1973). These afferents do not respond to mechanical stimulation with thermally neutral probes. These afferents are thought to subserve the percept of cool.

5.08.2.3 Classification of Nociceptors Based on Molecular Markers

In addition to a classification that is based on receptive properties, nociceptive afferents can be categorized using molecular markers that are expressed in their cell bodies or on their cell membrane. Markers that have been used for this purpose include neuropeptides, enzymes, and proteins involved in signal transduction, receptors for growth factors, and other molecules on the cell surface.

The somata of slowly conducting nociceptive afferents are small. In contrast to large cells that can be labeled with RT97, an antibody that is directed against neurofilament protein (NF200), only some of the small cells can be labeled with RT97. Small, RT97-positive neurons most likely represent the somata of Aδ nociceptive fibers. RT97-negative cells likely represent unmyelinated neurons.

Nociceptive afferents are commonly classified as peptidergic or nonpeptidergic (Figure 5). Peptidergic cells express substance P (SP) and/or calcitonin gene-related peptide (CGRP) or somatostatin (SOM). In rats, about 50% of neurons are peptidergic (Lawson, S. N., 1992). Peptidergic cells also express the tyrosine kinase receptor A (TrkA), the receptor for nerve growth factor (NGF), suggesting that they are NGF dependent. In addition, peptidergic cells express the TRPV1 channel that is activated by noxious heat stimuli and protons and also mediates the responsiveness to vanilloids (capsaicin and resiniferatoxin). Centrally, peptidergic neurons project to lamina I and the outer lamina II of the dorsal horn.

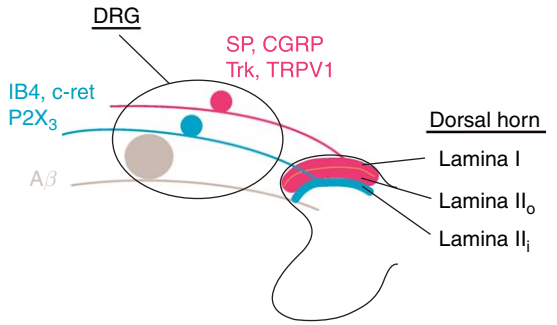

Figure 5 Small-diameter dorsal root ganglion neurons can be divided into two classes based on molecular markers in their cell bodies. The neurons in one class (shown in pink) are tyrosine kinase receptor A (TrkA), transient receptor potential V1 (TRPV1) channel, calcitonin gene-related peptide (CGRP), and substance P (SP)-positive and project to lamina I and lamina II_o of the dorsal horn. The neurons in the other class (shown in blue) are IB4, c-ret, and $P2X_3$ positive and project to lamina II_i.

Nonpeptidergic cells contain fluoride-resistant acid phospatase (FRAP) and bind the plant lectin IB4 from *Griffonia simplicifolia*. About 50% of dorsal root ganglion cells are IB4 positive ($IB4^+$). In contrast to peptidergic cells, $IB4^+$ neurons depend on glial cell-derived neurotrophic factor (GDNF) and they express the necessary receptors, tyrosine kinase Ret (c-ret), and glial cell-derived neurotrophic factor receptors (GDNFRα1–4). $IB4^+$ cells express the $P2X_3$ receptor, a purinergic ligand-gated ion channel that is activated by adenosine triphospate (ATP). The central terminals of $IB4^+$ neurons terminate in the inner sheet of lamina II. Some $IB4^+$ neurons also express *m*as-*r*elated *g*enes A and D (mrgA and mrgD) or *m*as-*r*elated *G p*rotein-coupled *r*eceptors A and D (mrgprA and mrgprD) (Dong, X. *et al.*, 2001). $IB4^+$ and $mrgA^+$ neurons are mostly $P2X_3^-$ and express c-ret only at a low level. In contrast, $IB4^+$ and $mrgD^+$ neurons are also $P2X_3^+$ and express high levels of c-ret (Dong, X. *et al.*, 2001). $IB4^+$ fibers innervate many tissues of the body, including muscle and visceral organs. However, $IB4^+/mrgpd^+$ fibers are exclusively found in skin, where they terminate in the stratum granulosum of the epidermis, whereas CGRP-containing nerve fibers end less superficial in the stratum spinosum (Zylka, M. J. *et al.*, 2005). In addition, $IB4^+/mrgpd^+$ neurons appear to project to a distinct lamina of the dorsal horn, that is, between the outer and the inner sheet of lamina II. Thus peptidergic and nonpeptidergic nociceptive neurons appear to differ in growth factor dependency, in ion channel expression involved in signal transduction, in their peripheral terminations, and in their central, dorsal horn projections.

While the classification into peptidergic and nonpeptidergic cells is commonly used, it should be emphasized that there is an overlap of marker expression between peptidergic and nonpeptidergic neurons. For example, some $IB4^+$ neurons express TRPV1or CGRP. Furthermore, there are considerable species differences in the expression and coexpression of these markers. For example, in mice only a minority of $IB4^+$ cells express TRPV1 (Zwick, M. *et al.*, 2002), whereas in rats the majority of $IB4^+$ and $IB4^-$ cells express TRPV1 (Michael, G. JC. and Priestley, J. V., 1999). Finally, the expression of these markers is not rigid but changes during development and after injury. Thus, peripheral inflammation increases the proportion of cells expressing neuropeptides, whereas following nerve injury, the proportion of cells expressing neuropeptides decreases.

5.08.3 Efferent and Trophic Functions of Nociceptors

In addition to serving the afferent function of signaling pain sensation, nociceptors also mediate efferent effects such as the flare that surrounds an injury site. This flare is thought to be due to an axonreflex mechanism, since the flare is absent in denervated tissue but present when a cutaneous nerve is blocked at a proximal location. When an action potential is initiated in the cutaneous terminals, it propagates not only orthodromically up the axons toward the CNS but also antidromically into peripheral branches of the nerve fiber where it causes the release of neuropeptides that are present in the terminals (Figure 6). Since afferent and efferent paths of this reflex arc are within the same axon, this reflex has been coined an axon reflex. The peripherally released neuropeptides include SP, neurokinin A (NKA), CGRP, vasoactive intestinal polypeptide (VIP), and SOM.

In animals, SP and CGRP are released from capsaicin-sensitive nerve endings and may induce vasodilation and plasma extravasation. These neuropeptides are also thought to stimulate epidermal cells (e.g., Langerhans' cells and kerotinocytes) and to play a role in immunological processes such as the migration of leukocytes at sites of tissue injury. In human skin, the antidromic release of neuropeptides is thought to lead to vasodilation, but not plasma extravasation (Schmelz, M. and Petersen, L. J., 2001). The area of the axon reflexive flare in humans is much

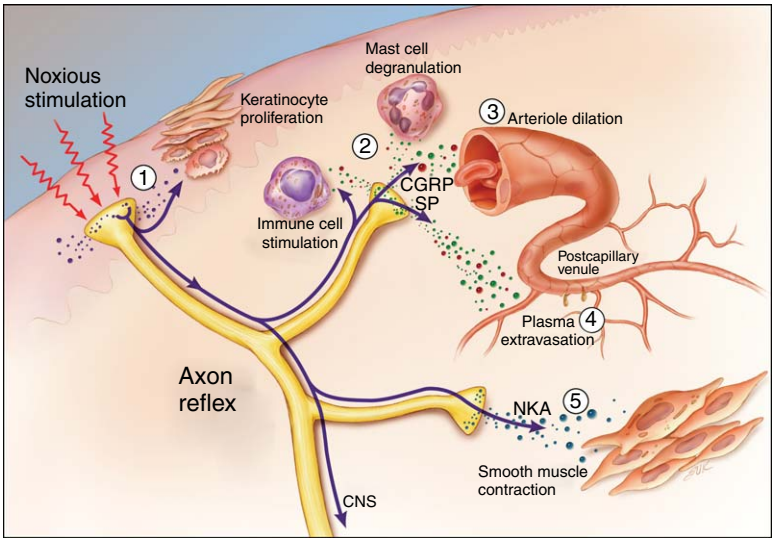

Figure 6 Nociceptors have an efferent function. Noxious stimulation of the nociceptor terminals leads to action potential propagation not only to the CNS but also into other peripheral branches of the nociceptor where they cause the release of neuropeptides such as calcitonin gene-related peptide (CGRP), SP, or NKA. The release of neuropeptides from nociceptors can lead to (1) proliferation of keratinocytes, (2) stimulation of immune cells or degranulation of mast cells, (3) vasodilation, (4) plasma extravasation, and (5) smooth muscle contraction. Artwork by Ian Suk, Johns Hopkins University. Reproduced from Meyer, R. A., Ringkamp, R., Campbell, J. N., and Raja, S. N. 2005. Peripheral Mechanisms of Cutaneous Nociception. In: Wall and Melzack's Textbook of Pain, 5 edn. (*ed*. M. K. S. McMahon), pp. 3–34. Elsevier, with permission from Elsevier.

Table 2 Roles of different afferents in acute pain sensation

Percept	*Afferents responsible*
Heat pain on glabrous skin	CMHs
First pain to heat on hairy skin	Type II A-fibers
Second pain to heat on hairy skin	CMHs
Pain to sustained heat stimulus	Type I AMHs
Pain to sharp mechanical stimulus	A-fiber nociceptors
Pain to sustained pressure	C-MIAs
Pain to capsaicin	C-MIAs, A-MIAs

larger than the receptive field size of CMHs. C-MIAs have large receptive field sizes and could therefore account for the large area of flare. The high threshold needed to induce flare by electrocutaneous stimulation is also consistent with mediation by MIAs (Schmelz, M. *et al*., 2000).

5.08.4 Acute Pain Sensations and Nociceptor Activity

We now address the role of different classes of nociceptors in acute pain sensation (Table 2). To do this, psychophysical measurements of pain intensity in human subjects are compared to the neuronal response in nociceptors when both are exposed to identical stimuli. A number of different scaling techniques can be used by humans including a visual analog scale (VAS) and the magnitude estimation technique (see Box 3)

5.08.4.1 Pain from Heat Stimuli

5.08.4.1.1 Heat pain from glabrous skin is signaled by C-fiber nociceptors

Near pain threshold, only two classes of fibers respond to heat stimuli applied to the glabrous skin, warm fibers, and CMHs. Type II A-fiber nociceptors are not found on glabrous skin, and type I AMHs have high heat thresholds. Warm fibers respond to gentle warming, but their response reaches a peak at temperatures at or below the threshold for pain (Figure 7) and then decreases for higher temperatures. In contrast, the response of CMHs starts at or below the heat pain threshold, and the response increases with temperature into the painful range. The stimulus–response functions for CMHs and for human pain ratings match well (Figure 7, Box 3).

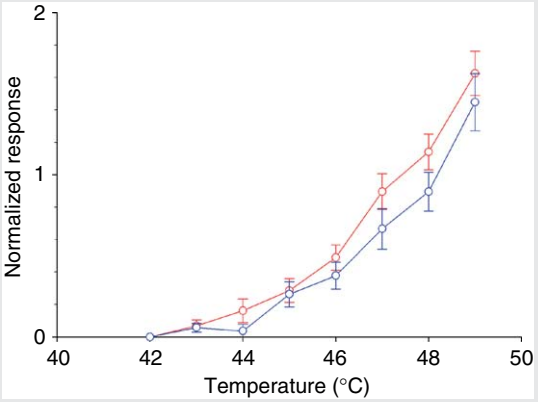
There are a number of additional lines of corroborating evidence that CMHs encode heat pain sensation from glabrous skin: First, the long reaction time in human subjects to step increases in temperature is

Box 3 Psychophysical measurements of pain

A number of different techniques exist to measure the intensity of pain in human subjects. One of the most commonly used techniques is the visual analog scale (VAS) in which descriptors of pain are placed along the edge of the scale. This technique is very useful for measuring moderate levels of pain but suffers from ceiling effects for high levels of pain (i.e., once the subjects rates a given stimulus near the top of the scale, there is little room left for stimuli that may be much more intense).

Another method that is extremely useful for correlations with neural responses is the technique of magnitude estimation. In this procedure, the subjects are presented a moderately painful stimulus and asked to assign a number (e.g., 100) to their perceived intensity of that stimulus. Subsequent stimuli are then rated relative to this modulus. For example, if the next stimulus is twice as intense, the rating would be 200; half as intense, the rating would be 50. This technique does not suffer from ceiling effects, since the subject can use whatever numbers are needed to indicate the relative intensity of the stimulus. This is basically a ratio scale, since all ratings are made relative to the modulus. Ideally, the modulus is repeated during the course of the experiment to refresh the subject's memory.

An example of the use of the magnitude estimation technique to measure the intensity of heat pain in human subjects is shown in the figure.



In this experiment, the glabrous skin of the hand was exposed to a random presentation of temperatures ranging from 41 to 49 °C in 1 °C increments. The random sequence was preceded by the presentation of a 45 °C stimulus that was used by the subjects to establish the reference rating (i.e., their modulus). To combine data across subjects who used different numbers for their modulus, data were normalized by dividing the ratings to a given stimulus by the ratings to the first stimulus. An identical sequence of temperatures was presented to the receptive field of CMHs recorded from the anesthetized monkey. The data across the population of CMHs were normalized by dividing the response of the nociceptors to a given temperature by the response to the initial 45 °C stimulus. The close correlation between the psychophysical data and the electrophysiological data provides strong evidence that CMHs encode heat pain from glabrous skin. Figure reproduced from Meyer, R. A. and Campbell, J. N. 1981b. Peripheral neural coding of pain sensation. Johns Hopkins APL Tech. Dig. 2, 164–171, with permission from APLTD.

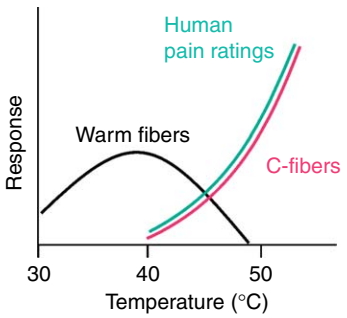


Figure 7 C-fiber nociceptors signal heat pain sensation from the glabrous skin. The response of warm fibers reaches a peak at relatively low temperatures and decreases as the temperature approaches the painful range. The response of C-fiber nociceptors starts near the pain threshold and increases with temperature. The pain ratings of human subjects closely matches the response profile of C-fiber nociceptors.

consistent with peripheral action potential propagation in the slowly conducting unmyelinated fibers. Second, selective blockade of peripheral conduction in myelinated fibers does not abolish heat pain sensation. Third, the fatigue to repeated heat stimuli described above for CMHs is also observed in psychophysical studies of pain to repeated heat stimuli. Fourth, in human microneurography experiments, intraneural electrical stimulation of presu-mably single CMHs elicits pain sensations.

5.08.4.1.2 First pain to heat on hairy skin is signaled by type II A-fiber nociceptors

In the hairy skin of the arm, stepped increases in temperature lead to a double pain sensation; an initial pricking pain is followed after a short lull by a

burning sensation (Figure 8). The reaction time to the pricking pain sensation is too short for conduction by slowly conducting unmyelinated fibers in the periphery. In addition, first pain sensation is blocked during a selective blockade of myelinated fibers.

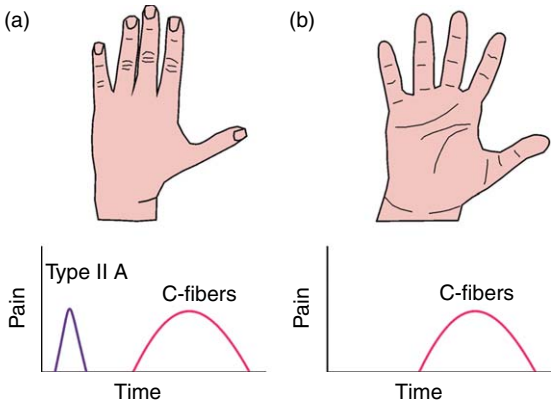

Figure 8 Heat pain on hairy and glabrous skin. (a) A heat stimulus on hairy skin leads to a dual pain sensation, an initial pricking pain followed by a burning pain. This is consistent with the finding that type II A-fiber nociceptors are found on hairy skin. (b) A heat stimulus on glabrous skin leads to burning pain only. Type II A-fibers are not found on glabrous skin.

These findings suggest that the first pain sensation to heat is mediated by myelinated afferents.

The type II A-fiber nociceptors are ideally suited to signal first pain sensation. The quick burst in action potential activity at the onset of a heat stimulus seen in type II A-fiber nociceptors is consistent with the percept of a short-lasting pricking sensation. The heat threshold of type II A-fiber nociceptors is also near the heat threshold for first pain sensation. The lack of type II fibers in glabrous skin is consistent with the absence of first pain to heat on the glabrous skin (Figure 8).

Figure 9 illustrates the neural responses to stepped increases in temperature in hairy skin. The heat stimulus activates a population of CMHs and type II A-fiber nociceptors with receptive fields that overlap the area of the heat stimulus. At the cutaneous terminals, both classes of fibers respond relatively quickly to the heat stimulus, but the response of the type II A-fibers rapidly adapts. As the neural signal propagates up to the CNS, these responses separate in time due to the conduction velocity differences of the myelinated and unmyelinated fibers. The signal from the type II fibers arrives at the CNS much sooner than the response of the

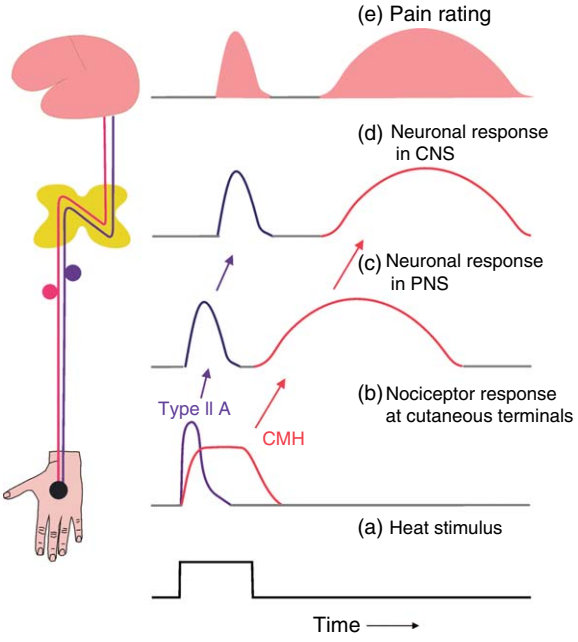

Figure 9 First pain to heat on hairy skin is signaled by A-fiber nociceptors. A stepped heat stimulus on hairy skin (a) leads to a dual pain sensation, a sharp pain followed after a lull by a burning pain (e). Heat stimuli near pain threshold activate two classes of nociceptors on hairy skin, type II A-fibers and C-fiber mechanoheat-sensitive afferents (CMHs) (b). The signal that reaches the central nervous system (CNS) is both delayed and broader than the signal at the receptor terminals. The A-fibers have a faster conduction velocity than the C-fibers and therefore their signals arrive at the CNS with less delay. The broadening of the signal is due to the variation in conduction velocity across the population of fibers that respond.

CMHs. In addition, the signals from each class of afferents become broader because of the variation in conduction velocity in each population of fibers that respond to the stimulus. The double pain response reflects the different arrival times at the CNS of neural signals from these two classes of afferents. This difference in arrival time is more apparent for stimuli applied to the distal extremities where the conduction lengths are long. A double pain sensation is not as apparent at more rostral locations (e.g., the face) where the conduction distances are short.

5.08.4.1.3 Pain to prolonged heat stimuli is signaled by type I A-fiber nociceptors

A long-duration heat stimulus applied to the glabrous skin produces pain that lasts through out the stimulus. However, the response of CMHs adapts to a long heat stimulus. In contrast, the response of type I A-fiber nociceptors builds during the course of a prolonged heat stimulus (Figure 3). Therefore, type I A-fiber nociceptors are thought to account for the pain to sustained high-intensity heat stimuli.

5.08.4.2 Pain from Controlled Mechanical Stimuli

5.08.4.2.1 Sharp pain is signaled by A-fiber nociceptors

The force thresholds for sharpness and pain from cylindrical objects increase in direct proportion with the circumference of the probe (Greenspan, J. D. and McGillis, S. L. B., 1991). As noted above, a similar relationship exists between probe circumference and the response of nociceptors. Sharp pain sensation is dramatically reduced in the presence of a selective blockade of A-fiber conduction. In addition, the reaction time for perception of sharp pain is short. Thus, A-fiber nociceptors appear to be primarily responsible for encoding the percept of sharp pain. Prolonged topical application of capsaicin leads to a substantial decrease in heat pain sensitivity but does not greatly affect mechanical pain sensibility (Magerl, W. *et al.*, 2001). This suggests that the A-fibers involved in sharp pain are insensitive to capsaicin (likely, type I AMHs).

5.08.4.2.2 Pain from tonic pressure is signaled by C-fiber MIAs

Firm pressure does not hurt if applied for short periods of time but becomes painful when sustained for long periods of time. The response of mechanically sensitive nociceptors adapts to a constant mechanical stimulus. In contrast, C-fiber MIAs develop a response during a maintained stimulus (Schmidt, R. *et al.*, 2000). In addition, the pain to tonic pressure does not disappear during a selective A-fiber block (Andrew, D. and Greenspan, J. D., 1999). Thus, it appears that C-fiber MIAs encode the pain to tonic pressure.

5.08.4.3 Cold Pain Sensation

The threshold for cold pain sensation is around 14 °C on hairy skin. This is much farther from resting skin temperature (33 °C) than the threshold for heat pain (around 45 °C). In addition, the slope of the stimulus–response function for cold pain is shallower than that for heat pain (Morin, C. and Bushnell, M. C., 1998). Cold pain appears to be signaled, at least in part, from deep receptors since topical anesthetics do not abolish it and the latency for the perception of cold pain is long.

The majority of nociceptors respond to ice applied to the receptive field. A nonselective cation channel (TRPA1) has been identified that has an activation threshold (18 °C) near the cold pain threshold and is found in a subset of nociceptors (Story, G. M. *et al.*, 2003). However, the role of this channel in signaling the pain to a noxious cold stimulus is controversial (Bautista, D. M. *et al.*, 2006; Kwan, K. Y. *et al.*, 2006). In the presence of an A-fiber block, gentle cooling stimuli become painful. It is thought that cold-evoked activity in A-delta cold fibers normally inhibits pain produced by activation of nociceptors.

5.08.4.4 Capsaicin-Evoked Pain

Capsaicin, the active ingredient in hot peppers, produces a burning percept upon contact with mucous membranes and produces intense pain that lasts for several minutes when injected into the skin. Topical or intradermal capsaicin can also lead to a marked desensitization to heat stimuli. The TRPV1 channel expressed by many nociceptors is thought to be responsible for the pungency of capsaicin. Injection of capsaicin into the receptive field of CMHs produces a weak response and can lead to a desensitization of the afferent to heat. Injection of capsaicin into the receptive field of A-fiber and C-fiber MIAs produces a long-lasting, strong response, suggesting that these afferents are responsible for the pain from capsaicin.

5.08.5 Hyperalgesia

A tissue injury can lead to an enhancement of pain sensibility called hyperalgesia. Hyperalgesia is characterized by a leftward shift in the stimulus–response function relating pain intensity to stimulus intensity (Figure 10(a)). There is a decrease in the threshold for pain, an increase in the pain to suprathreshold stimuli, and ongoing pain. The electrophysiological correlate for hyperalgesia is sensitization of nociceptive neurons (Figure 10(b)), either of peripheral nociceptors (peripheral sensitization) or of central neurons involved in processing nociceptive input (central sensitization) or both. Sensitization is characterized by a leftward shift in the neural response at different stimulus intensities. There is a decrease in the threshold for eliciting a response, an increase in the response to suprathreshold stimuli, and spontaneous activity.

Two zones of hyperalgesia are readily identified (Figure 11). Primary hyperalgesia occurs at the site of injury and is characterized by hyperalgesia to both heat and mechanical stimuli. Secondary hyperalgesia occurs in the uninjured tissue surrounding the site of injury and is characterized by hyperalgesia to mechanical but not heat stimuli. This dichotomy provides evidence that the mechanisms for primary and secondary hyperalgesia differ.

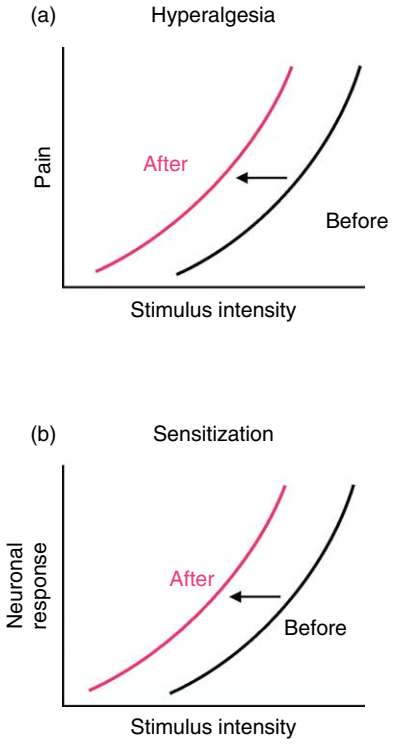

Figure 10 Hyperalgesia and sensitization. (a) Hyperalgesia is characterized by a leftward shift in the stimulus function relating pain intensity to stimulus intensity. (b) Sensitization is characterized by a leftward shift in the stimulus function relating neural response to stimulus intensity.

5.08.5.1 Primary Hyperalgesia

5.08.5.1.1 Hyperalgesia to heat is mediated by primary afferent sensitization

Hyperalgesia to heat is prevalent after a cutaneous injury and after inflammation. Substantial evidence indicates that sensitization of primary afferent nociceptors to heat accounts for this hyperalgesia. For example, a burn injury to the glabrous skin of the hand leads to marked hyperalgesia to heat and sensitization of type I AMHs to heat (Figure 12). Although a burn to the glabrous skin does not lead to sensitization of CMHs, a burn injury to the hairy skin does. This suggests that the propensity to sensitize is a function of skin type. Whether this is due to differences in the milieu or due to differences in the properties of the neurons is not known.

Hyperalgesia to heat can also develop after inflammation. When a cocktail of inflammatory mediators is injected into the receptive field of nociceptive afferents, marked sensitization to heat stimuli is observed.

5.08.5.1.2 Hyperalgesia to mechanical stimuli

Hyperalgesia to mechanical stimuli also occurs after a cutaneous injury and after inflammation. A number of possible mechanisms may account for this mechanical hyperalgesia.

Nociceptor sensitization. Although a burn injury leads to sensitization of nociceptors to heat stimuli, the mechanical threshold of nociceptors is not lowered, suggesting that this injury does not produce sensitization to mechanical stimuli. However, nociceptors are sensitized to mechanical stimuli in situations of inflammation. For example, injection into the receptive field of inflammatory substances leads to a sensitization of MIAs to mechanical stimuli. Inflammation of the knee joint also leads to a sensitization of MIAs to mechanical stimuli.

Spatial summation. When a burn injury is applied at the edge of the receptive field of a nociceptor, the receptive field expands into the area of injury. As a result, a mechanical stimulus in the area of injury evokes a response in a greater number of nociceptive

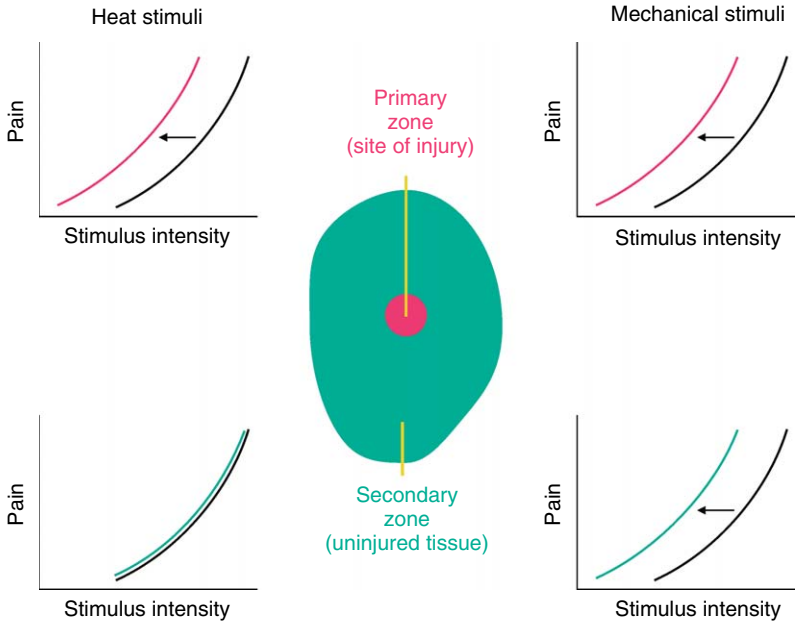

Figure 11 Primary and secondary hyperalgesia. There are two forms of hyperalgesia. Primary hyperalgesia occurs at the site of injury and is characterized by hyperalgesia to both mechanical and heat stimuli. Secondary hyperalgesia occurs in the uninjured tissue surrounding the injury site and is characterized by hyperalgesia to mechanical but not heat stimuli.

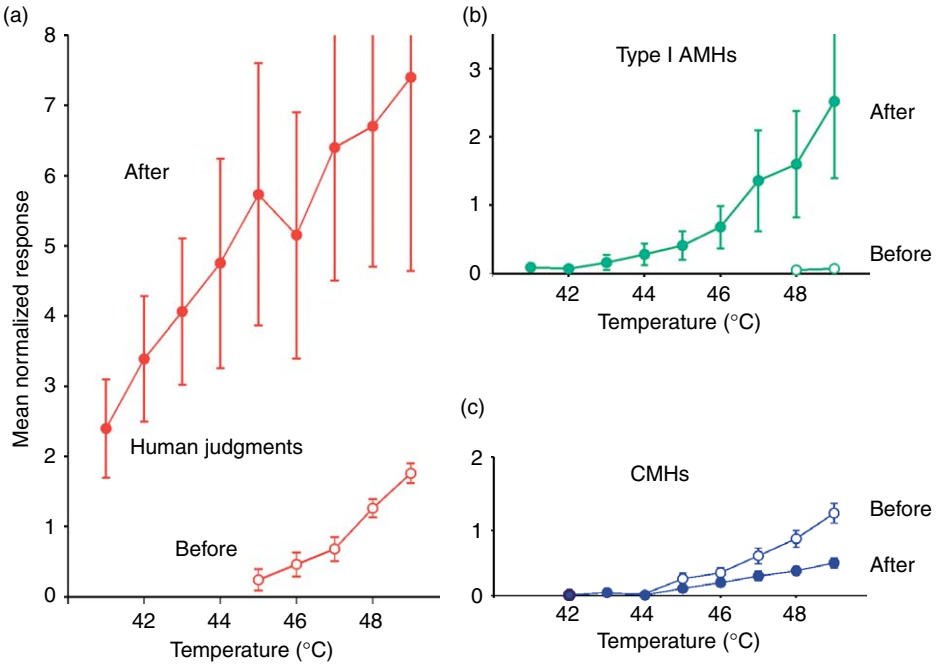

Figure 12 Primary hyperalgesia to heat is signaled by sensitization of primary afferent nociceptors. (a) A burn injury to the glabrous skin of human subjects leads to a dramatic increase in pain ratings to heat stimuli. (b) The same burn injury leads to a marked sensitization of type I AMHs in the anesthetized monkey. (c) This burn injury led to a desensitization of CMHs on glabrous skin. However, burn injuries to CMHs on hairy skin do lead to sensitization. Adapted from Meyer, R. A. and Campbell, J. N. 1981a. Myelinated nociceptive afferents account for the hyperalgesia that follows a burn to the hand. Science 213, 1527–1529, with permission from AAAS.

afferents. This will lead to spatial summation in the CNS that would be expected to produce more pain.

Central sensitization. Peripheral sensitization appears to account, at least in part, for hyperalgesia to mechanical stimuli. In addition, the central sensitization phenomena to be described below for secondary hyperalgesia may also play a role in primary hyperalgesia to mechanical stimuli.

5.08.5.1.3 Inflammatory mediators and nociceptor sensitization

Injury leads to the local release of various endogenous substances that excite or modulate the terminals of primary-afferent nociceptors (Figure 13). For example, bradykinin is released on tissue injury (e.g., from the plasma) and can excite and sensitize nociceptor terminals. Intradermal injection of bradykinin produces pain and hyperalgesia. Serotonin, histamine, and prostaglandin can also be released from mast cells and alter nociceptor terminal sensitivity. Tissue injury can also lead to the release or leakage of adenosine and its derivatives (e.g., ATP) into the extracellular space and could therefore activate sensory terminals. Low pH levels found in inflammed tissue activate and modulate nociceptor terminals. During inflammation, cytokines (e.g., interleukins and tumor necrosis factor alpha) are released by a variety of cells (e.g., macrophages) and are not only involved in regulating the inflammatory process but may also act as algesic substances either by directly activating nociceptive endings or by increasing their sensitivity to natural stimuli.

As illustrated in Figure 13, these agents can act directly at specialized receptors on the nociceptor terminal to excite the ending or to alter the sensitivity of the ending. The molecular mechanisms of transduction and sensitization are discussed in more detail in Chapter Molecular Biology of the Nociceptor/Transduction.

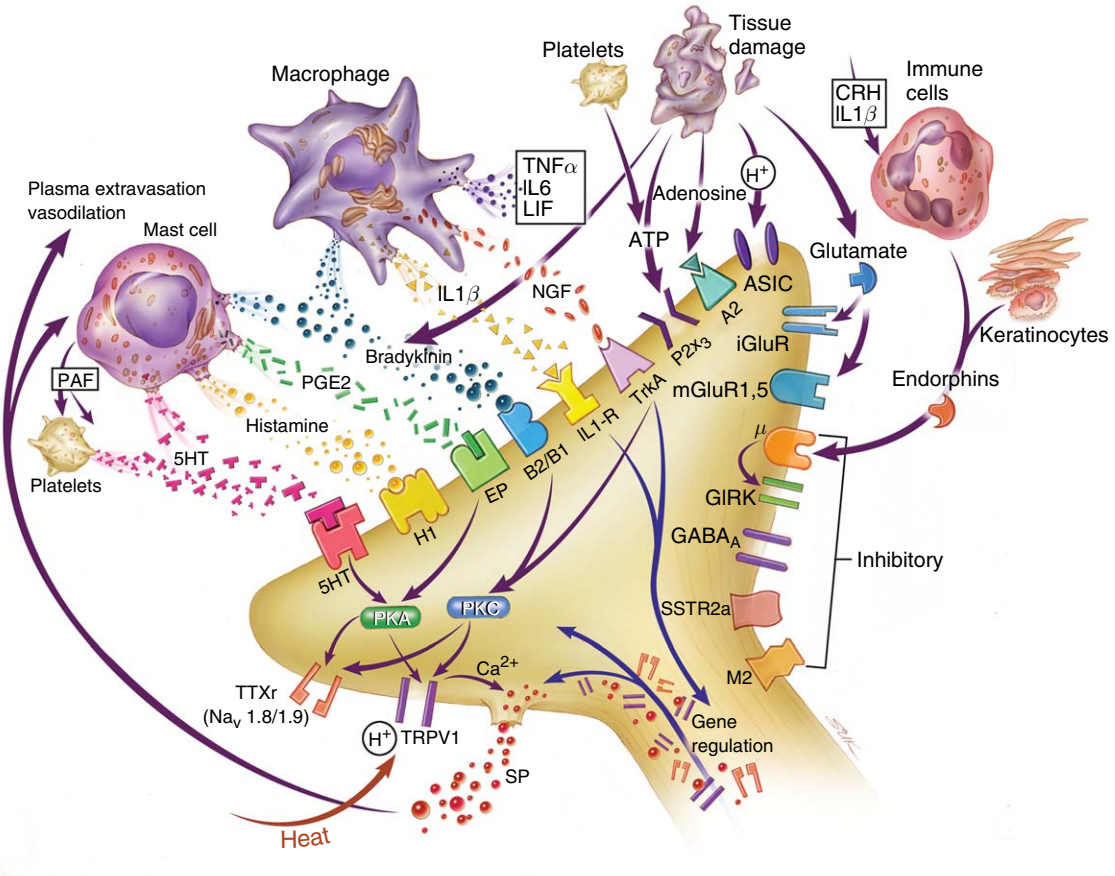

Figure 13 Inflammatory mediators act on specific receptors located at the nociceptor terminals. Artwork by Ian suk, Johns Hopkins University. Reproduced from Meyer, R. A., Ringkamp, R., Campbell, J. N., and Raja, S. N. 2005. Peripheral Mechanisms of Cutaneous Nociception. In: Wall and Melzack's Textbook of Pain, 5 edn. (*ed*. M. K. S. McMahon), pp. 3–34. Elsevier.

5.08.5.2 Secondary Hyperalgesia

Secondary hyperalgesia is characterized by hyperalgesia to mechanical but not heat stimuli. Two distinct forms of mechanical hyperalgesia have been reported (Figure 14). Punctate hyperalgesia (or static hyperalgesia) is characterized by hyperalgesia to sharp stimuli that normally cause pain (e.g., stiff von Frey probes and pin prick). Stroking hyperalgesia (or dynamic hyperalgesia or allodynia) is characterized by pain to a light moving touch (e.g., stroking of the skin with a soft brush) but not blunt pressure.

5.08.5.2.1 Sensitization of primary afferent nociceptors does not occur

One possible explanation for secondary hyperalgesia is that the sensitization process that occurs at the site of injury spreads to adjacent uninjured tissue. In a manner similar to that described above for the axon-reflexive flare response, the nerve endings could release not only vasoactive substances but also substances that produce sensitization of nociceptive terminals. However, a number of lines of evidence suggest that spreading sensitization does not occur. For example, burn or mechanical injuries or mustard oil application to one half of the receptive field of nociceptors lead to sensitization of that part of the receptive field but not of the uninjured part of the receptive field. In addition, antidromic electrical stimulation of nociceptors, which should lead to the release of these putative sensitizing substances from the terminals, does not lead to sensitization. Also, the area of flare is generally smaller than the area of hyperalgesia. In addition, flare can be induced by substances (e.g., histamine injection) that do not lead to the development of hyperalgesia. Finally, flare can spread across the midline of the body, but hyperalgesia does not.

	Stroking hyperalgesia (allodynia)	Punctate hyperalgesia (static hyperalgesia)
Adequate stimulus	Light stroking	Punctate stimuli
Area	Small	Large
Duration	Short	Long
Central sensitization	Yes	Yes
Primary afferent signal	Low-threshold mechano-receptors	Nociceptors

Figure 14 Two forms of secondary hyperalgesia to mechanical stimuli. The properties of punctate and stroking hyperalgesia are different, suggesting that the neural mechanisms may differ.

5.08.5.2.2 Central mechanisms of secondary hyperalgesia

The preponderance of experimental data indicate that secondary hyperalgesia is the result of plasticity in the CNS often called central sensitization (Figure 15). This central sensitization is initiated by

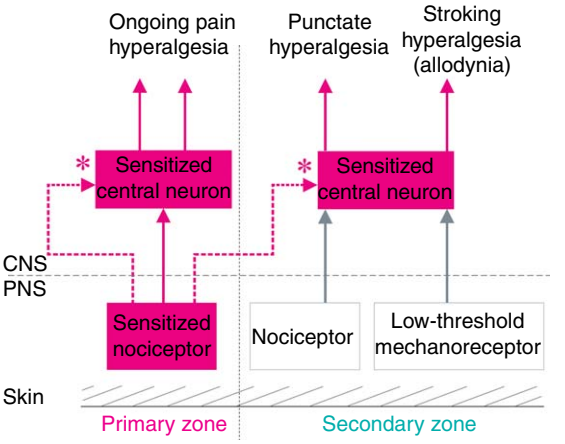

Figure 15 Secondary hyperalgesia is due to central sensitization. An injury or inflammation leads to activation and sensitization of nociceptors in the zone of primary hyperalgesia. Activity in the peripheral nociceptors produces a state of central plasticity in the CNS called central sensitization (*). This sensitization spreads to central neurons with input from adjacent, uninjured afferents. Sensitization to input from nociceptors accounts for punctate hyperalgesia. Sensitization to input from low-threshold mechanoreceptors accounts for stroking hyperalgesia (or allodynia).

neural activity in primary-afferent nociceptors and is already apparent at the level of the dorsal horn.

Compelling evidence for central sensitization comes from an experiment in which capsaicin was injected into both the forearms of human volunteers (LaMotte, R. H. *et al.*, 1991). In the control arm, the capsaicin injection produced intense pain and led to the development of a flare and a large zone of secondary hyperalgesia. In the test arm, the nerve supplying the forearm was anesthetized at a proximal site prior to the injection. The injection did not hurt but did lead to the development of an axon-reflexive flare, indicating that the nociceptors had been activated and were able to release vasoactive substances (and also putative sensitizing substances). Three hours after the capsaicin injection, there was no hyperalgesia on the test arm, but the control arm still had a large zone of secondary hyperalgesia.

The characteristics of stroking and punctate hyperalgesia are different, suggesting that the neural mechanisms are different (Figure 14). For example, the area of punctate hyperalgesia is typically larger than the area of stroking hyperalgesia. In addition, the duration of punctate hyperalgesia is longer than the duration of stroking hyperalgesia. Stroking hyperalgesia appears to be more dependent on ongoing input from nociceptors, since cooling or anesthetizing the site of injury substantially reduces the zone of stroking hyperalgesia without greatly affecting the zone of punctate hyperalgesia. As described below, both forms of secondary hyperalgesia are thought to be due to central sensitization mechanisms.

Stroking hyperalgesia appears to be due to central sensitization to input from low-threshold myelinated mechanoreceptors (Figure 15). The light stroking stimulus that produces pain in the secondary zone readily activates low-threshold mechanoreceptors but not nociceptors. Compelling evidence comes from an experiment in which intraneural microstimulation was performed in human volunteers (Torebjörk, H. E. *et al.*, 1992). A low-intensity, fixed-frequency electrical stimulus produced a tactile percept referred to a small area on the foot. Capsaicin was then injected adjacent to this area and produced secondary hyperalgesia that spread into this area. When the electrical stimulation was repeated at the same intensity and frequency, it now produced pain. This electrical stimulation of myelinated fibers bypassed the natural transduction apparatus and indicates that there was central sensitization to input from myelinated fibers. Additional evidence comes from studies which show that selective peripheral blockade of myelinated fibers (with conduction maintained in unmyelinated fibers) leads to the disappearance of stroking hyperalgesia.

Punctate hyperalgesia appears to be due to central sensitization to input from nociceptors (Figure 15). Punctate hyperalgesia, and not stroking hyperalgesia, developed when capsaicin was injected into the arm of a patient with a selective, large-fiber neuropathy, indicating that small myelinated or unmyelinated fibers are involved. In addition, enhanced pain to woolen fabrics is observed in the zone of secondary hyperalgesia. Since the prickliness of woolen fabrics is encoded by activity in nociceptors, not mechanoreceptors, activity in nociceptors likely accounts for this hyperalgesia. Selective nerve blocks revealed that punctate hyperalgesia disappeared when Aδ nerve fibers were blocked, suggesting that Aδ nociceptors are important. The nociceptors appear to be capsaicin insensitive since topical application of capsaicin produced desensitization to heat but did not eliminate punctate hyperalgesia produced by a subsequent injection of capsaicin adjacent to the treated area (Magerl, W. *et al.*, 2001).

Glossary

allodynia Pain due to a stimulus that does not normally provoke pain.
alloknesis Itch elicited by light touching or stroking.
hyperalgesia An increased response to a stimulus which is normally painful.
hyperknesis Itch elicited by strong mechanical stimulation.
itch Unpleasant sensation associated with the desire to scratch.
nociceptor A receptor preferentially sensitive to a noxious stimulus or to a stimulus, which would become noxious if prolonged.
pain An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.
pruriceptor A sensory receptor preferentially sensitive to a pruritic stimulus.

5.09.1 Introduction and Definition of Itch

Itch is widely considered to be an unpleasant sensation associated with the desire to scratch. The definition of itch has recently been refined to include the following subcategories: pruriceptive (originating from skin damage), neuropathic (originating from nerve damage), neurogenic (originating centrally), and psychogenic (Yosipovitch, G. *et al.*, 2003). Itch is frequently associated with common insect bites or exposure to plants, providing a warning signal to remove the offending stimulus by scratching or rubbing the affected skin area. Itch can be experimentally elicited by cutaneous histamine and other chemicals (Schmelz, M. *et al.*, 2003b) and by electrical surface stimulation of the skin (Tuckett, R. P., 1982; Ikoma, A. *et al.*, 2005). However, itch also commonly occurs under a variety of skin conditions such as dry skin and contact or atopic dermatoses (eczema). Moreover, a variety of systemic disorders also have itching as a symptom (Krajnik, M. and Zbigniew, Z., 2001), in particular, liver dysfunctions such as cholestasis or biliary cirrhosis (Bergasa, N. V. *et al.*, 2000), and renal failure (Murphy, M. and Carmichael, A. J., 2000). Neuropathic itch is less commonly associated with lesions of the spinal cord (Dey, D. D. *et al.*, 2005) or other central structures. While itch associated with, for example, urticaria (hives) can be relieved by antihistamines acting at the H1 histamine receptor, itch associated with other skin conditions and systemic diseases is often refractory to antihistamines. This suggests that there may be other itch mediators and mechanisms in addition to histamine, the prototypical itch mediator in normal human skin.

Itch has historically been considered by some to be a low level of pain, and perhaps for this reason

the experimental study of itch has until now received much less attention compared to pain. Nevertheless, recent studies have provided exciting new evidence for the existence of itch-selective peripheral receptors and central pathways separate from those mediating pain (for recent reviews, see Stander, S. *et al.*, 2003; Twycross, R. *et al.*, 2003; Yosipovitch, G. *et al.*, 2003; 2004; Biro, T. *et al.*, 2005). This vignette will describe some of the recent advances in our understanding of itch mechanisms. An overview of the neural basis for itch versus pain is provided first, followed by consideration of animal itch models and, finally, possible itch mediators and mechanisms based on human and animal research.

5.09.2 Is Itch Distinct from Pain?

The concept that itch is on a continuum with pain prompted the frequency theory (von Frey, M., 1922), depicted schematically in Figure 1(a). A low firing rate in cutaneous nociceptors connected to a common central pathway elicits a sensation of itch, while high-frequency firing elicits pain. This idea is supported by observations that numerous stimuli, including histamine (Broadbent, J. L., 1955) elicit itch at low intensities and pain at higher intensities, and that both pain and itch are conveyed via the spinothalamic tract (White, J. C. and Sweet, W. H., 1969). The notion that itch and pain are conveyed by a common set of neurons, however, is belied by the following observations. Most importantly, itch can be elicited by focal electrical stimulation of the skin surface (Tuckett, R. P., 1982; Ikoma, A. *et al.*, 2005) or by intraneural microstimulation (Schmidt, R. *et al.*, 1993) and the itch becomes more intense but never takes on a painful quality as the stimulus frequency is increased. Conversely, pain elicited by intraneural stimulation never transforms to itch at lower frequencies (Ochoa, J. and Torebjörk, E., 1989; Handwerker, H. O. *et al.*, 1991). Furthermore, itch and pain rarely coexist and concurrent noxious stimulation, such as scratching, is well known to inhibit itch. Morphine and other opioids depress pain but frequently elicit or exacerbate itch, as discussed further below. Also, the behavioral manifestation of itch, scratching, is very different from manifestations of pain that often include withdrawal of the stimulated limb and/or escape reactions. Withdrawal from a noxious stimulus serves a protective function to prevent tissue damage, whereas scratching may represent an attempt to remove a pruritic stimulus that has already impinged upon tissue. In this regard, humans can localize the site of itch elicited by focal histamine application with errors of less than 10 mm, comparable to localization of punctate painful stimuli and only slightly worse than localization of tactile stimuli (Koltzenburg, M. *et al.*, 1993). This would aid the accuracy of scratches directed to an itchy site. However, two-point discrimination for histamine-induced itch is fairly poor, approximately 12–15 cm on forearm skin (Wahlgren, C. F and Ekblom, A., 1996) consistent with the very large

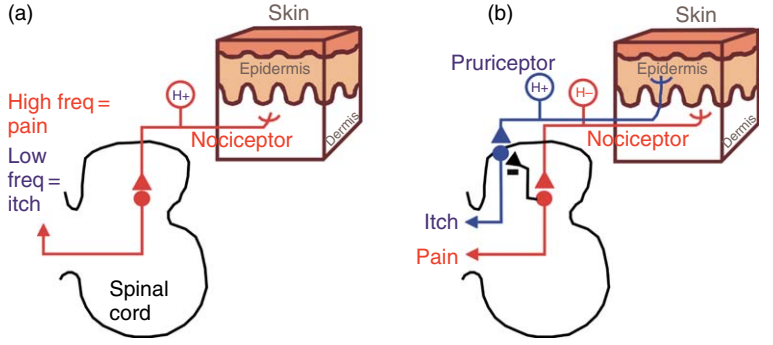

Figure 1 Theories of itch transmission. (a) Frequency theory. Both pruritic and noxious stimuli excite polymodal nociceptors in skin, which project to a common population of neurons in the spinal cord. These neurons signal itch at a low firing rate, and pain at a higher firing rate. H+: responsive to histamine. (b) Specificity (or selectivity) theory. Pruritic stimuli excite a selective population of pruriceptors in superficial epidermis that are histamine-sensitive (H+), and that project to a select population of spinal neurons (blue) in the superficial dorsal horn. Activity in this pathway signals itch. Dermal nociceptors project to a separate population of pain-signaling spinal neurons (red). Incorporated in this schematic is an inhibitory connection (black) from pain- to itch-transmitting neurons, reflecting the ability of noxious counterstimuli to inhibit itch.

innervation territories of putative pruriceptors (Schmelz, M. *et al.*, 1997) (see below).

For the reasons noted above, it has long been postulated that itch and pain are conveyed via separate central pathways, with pain capable of inhibiting itch transmission. This concept is depicted in Figure 1(b). The separate pathways for itch and pain constitute the classic specificity theory. Given recent evidence showing a relative, rather than absolute, sensitivity of potential itch-signaling fibers to pruritics, the term selectivity is more appropriate. The ability of pain to inhibit itch is incorporated by the black inhibitory neuron shown in Figure 1(b), although interactions between nociceptive and pruriceptive systems may conceivably occur at supraspinal as well as spinal levels.

5.09.3 Pain Inhibition of Itch

Numerous experimental studies have demonstrated suppression of itch in humans by a variety of counterstimuli including cooling, mustard oil, and electrical cutaneous field stimulation (Bickford, R. G., 1937; Gammon, G. D. and Starr, I., 1941; Murray, F. S. and Weaver, M. M., 1975; Frustorfer, H. *et al.*, 1986; Ward, L. *et al.*, 1996; Nilsson, H. J. *et al.*, 1997). This suppression undoubtedly underlies the antipruritic effect of scratching. Opioids acting at the μ -opioid receptor depress pain, yet frequently induce or exacerbate itch in human patients (Bromage, P., 1981; Bromage, P. R. *et al.*, 1982; Morgan, M., 1987; Ballantyne, J. C. *et al.*, 1988), suggesting that inhibition of tonic nociceptive activity facilitates itch transmission. Consistent with this, μ-opioid antagonists reduce histamine-induced itch (Heyer, G. *et al.*, 1997a). Intradermal injection of histamine at a site previously anesthetized by local anesthetic in human subjects resulted in markedly enhanced itch (Atanassoff, P. G. *et al.*, 1999). The authors postulated that histamine excites two types of peripheral receptor, one conveying itch and the other being antipruritic (i.e., exciting central itch-inhibitory neurons). Preferential local anesthetic blockade of the antipruritic fibers would unmask pruriceptive input leading to increased itch.

Scratching behavior in mice and monkeys induced by μ-opioids is reduced by κ-opioid agonists in mice (Togashi, Y. *et al.*, 2002; Umeuchi, H. *et al.*, 2003) and monkeys (Ko, M. C. *et al.*, 2003). The κ agonists are also analgesic, suggesting a complex interaction between pro- and antipruritic opioid receptor-mediated central mechanisms. One possible scenario consistent with this interplay between μ- and κ-opioids is shown in Figure 2.

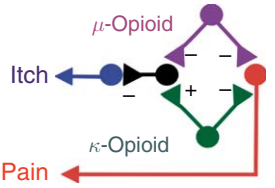

Figure 2 Schematic of opioid interactions with itch- and pain-signaling spinal neurons. μ-Opioid agonists (purple) inhibit pain and can induce or exacerbate itch, possibly by inhibiting interneurons (black) that tonically inhibit itch-transmitting neurons (blue), i.e., disinhibition. κ-Opioid agonists (dark green) also inhibit pain and may excite the inhibitory interneuron (black), thus inhibiting itch.

5.09.4 Peripheral and Spinal Mechanisms of Itch

Recent studies have provided evidence favoring the selectivity theory of itch depicted in Figure 1(b). Human microneurographic studies have uncovered a class of mechanically insensitive cutaneous receptors with slowly conducting unmyelinated afferent fibers that respond to cutaneous histamine over a time course that closely matches that of concomitant itch sensation (Figure 3; Schmelz, M. *et al.*, 1997). These potential itch receptors are called pruriceptors. Such histamine-responsive fibers also responded more weakly to prostaglandin E_2, serotonin, and acetylcholine, which were capable of inducing weak itch when delivered intradermally via microdialysis (Schmelz, M. *et al.*, 2003b). However, the fibers were not exclusively pruriceptive, as they also responded to capsaicin and bradykinin, which induce burning pain (Schmelz, M. *et al.*, 2003b), indicating that these fibers are itch-selective rather than itch-specific. These fibers could also be excited by electrical skin stimulation; however, the current intensities were much higher compared to electrical currents eliciting itch from the wrist (Ikoma, A. *et al*, 2005) suggesting that there may be additional pruriceptor subtypes.

Following the discovery of histamine-selective pruriceptors, a subpopulation of mechanically insensitive spinothalamic tract neurons in the cat superficial dorsal horn (lamina I) with temporally similar responses to histamine was identified (Andrew, D. and Craig, A. D., 2001) (Figure 3). Chemical selectivity was tested in four cases, with two additionally responding to mustard oil (which elicits burning pain) while the

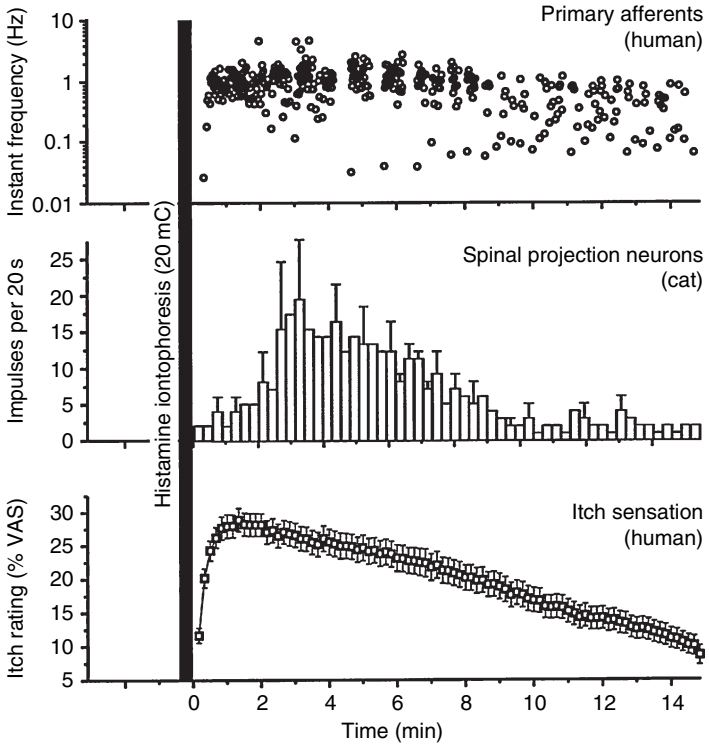

Figure 3 Time course of histamine-evoked response of an unmyelinated primary afferent fiber (upper panel), and mean responses of lamina I spinothalamic tract neurons (middle panel) in relation to itch sensation (lower panel). Vertical bar indicates time of delivery of histamine by iontophoresis to the skin. Adapted from Schmelz, M., Schmidt, R., Bickel, A., Forster, C., Handwerker, H. O., and Torebjork, H. E. 1997. Specific C-receptors for itch in human skin. J. Neurosci. 17, 8003–8008 and Andrew, D. and Craig, A. D. 2001. Spinothalamic lamina I neurons selectively sensitive to histamine: a central neural pathway for itch. Nat. Neurosci. 4, 72–76, with permission from Nature Publishing Group.

other two did not. These latter two units may be histamine-selective, while the units sensitive to both histamine and mustard oil resemble lamina I units in rats that gave prolonged response to serotonin (5-HT; also a pruritic) but usually also exhibited phasic responses to mustard oil, capsaicin, and other algogens (Jinks, S. L. and Carstens, E., 2002). An older study reported a fraction of wide dynamic range (WDR)-type neurons to respond to cutaneous application of cowhage (Wei, J. Y. and Tuckett, R. P., 1991). A recent study of identified spinothalamic tract neurons in primate found that about half responded to intradermal histamine, with all additionally responding to capsaicin (Simone, D. A. *et al.*, 2004). Moreover, neuronal responses to light mechanical stroking were unchanged after histamine, arguing against a role in alloknesis for these neurons. The authors conclude that such neurons are more likely to signal pain than itch. Similar findings were reported in the rat for neurons not identified by ascending projections (Carstens, E., 1997). Intradermal histamine produced an *N*-methyl-D-aspartic acid (NMDA) receptor-dependent expansion of lumbar neuronal receptive fields (Jinks, S. L. and Carstens, E., 1998) possibly reflecting central sensitization of pain rather than itch, as histamine may be algesic rather than pruritic in rats (see below; Jinks, S. L. and Carstens, E., 2002). Thus, the bulk of current evidence favors the concept of an itch-selective pathway, originating from mechanically insensitive, pruritogen-selective C-fiber afferents which project to lamina I spinothalamic tract neurons that, in turn, convey itch signals to the lateral thalamus and cortex (Figure 1(b)).

An alternative view is that spinal WDR neurons may also contribute to itch, much as they are thought to contribute to signaling pain together with nociceptive-specific neurons. Both pruritic (serotonin, histamine) and algesic chemicals (capsaicin, nicotine, formalin) excited neurons in overlapping regions of the superficial dorsal horn (laminae I–II) as assessed by c-fos (Jinks, S. L. *et al.*, 2002; Nojima, H. *et al.*, 2003b). The vast majority of single WDR neurons recorded in rat superficial dorsal horn responded to both pruritic and algesic chemical stimuli as well as

noxious heat (Jinks, S. L. and Carstens, E., 2000; 2002). Importantly, superficial dorsal horn neurons gave prolonged responses to serotonin that corresponded with the time course of serotonin-evoked scratching behavior in rats (Jinks, S. L. and Carstens, E., 2002) (Figure 4). The neuronal discharge rate during the response to serotonin was much lower compared to the phasic responses evoked by capsaicin and other algesic stimuli. Serotonin elicits dose-related scratching in rodents that was significantly reduced by opioid antagonists (Yamaguchi, T. *et al.*, 1999; Nojima, H. and Carstens, E., 2003a; Nojima, H. *et al.*, 2003b). Furthermore, c-fos expression in the superficial dorsal horn elicited by intradermal capsaicin, but not serotonin, was attenuated by morphine (Nojima, H. *et al.*, 2003b), consistent with serotonin being pruritic rather than algesic. If this is the case, then one must consider the possibility that pruriceptive information is being signaled by superficial WDR neurons, consistent with the frequency theory of itch.

In conclusion, exciting new information strongly favors the existence of an itch-selective pathway, but it would probably be wise not to completely discount the possible added contribution of nonselective neurons until more complete details about itch signaling have emerged. Future efforts to characterize itch-signaling neurons should test the following properties consistent with itch:

- Responses inhibited by scratching and other antipruritic counterstimuli.
- Responses facilitated by morphine (Jinks, S. L. and Carstens, E., 2000).
- Morphine facilitation blocked by κ-opioid antagonists.
- Responses inhibited by μ-opioid antagonists.
- Increased mechanical sensitivity consistent with alloknesis.

5.09.5 Alloknesis (Itchy Skin) and Sensitization

Intradermal injection of histamine elicits itch sensation, a wheal at the injection site, and a surrounding flare reaction due to histamine-evoked release of vasodilatory peptides (substance P (SP), calcitonin gene-related peptide). Light stroking in a broad area of normal skin surrounding the histamine injection can elicit itch, a phenomenon called itchy skin or alloknesis (Simone, D. A. *et al.*, 1991). The spread of alloknesis was prevented by local anesthesic block adjacent to the site of histamine injection, indicating that alloknesis is of neurogenic origin (Simone, D. A. *et al.*, 1991). Noxious punctuate stimulation in and around the region of alloknesis also elicits itch (hyperknesis) (Atanassoff, P. G. *et al.*, 1999).

The chronic itch of skin conditions such as atopic dermatitis suggests the possibility of peripheral or central sensitization along the itch-signaling pathway (Ikoma, A. *et al.*, 2004). Moreover, noxious stimuli such as acetylcholine, acid, heat, and pinprick, which normally evoke pain, instead elicit itch in atopic dermatitis patients (Vogelsang, M. *et al.*, 1995; Ikoma, A. *et al.*, 2004). A peripheral sensitization of

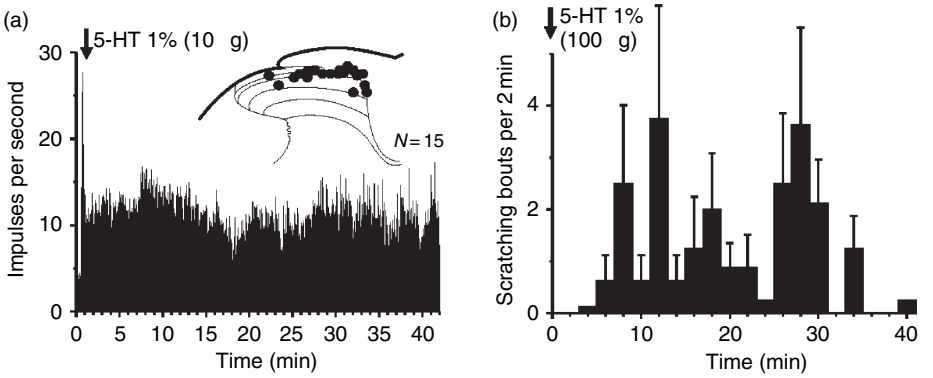

Figure 4 Prolonged responses of superficial dorsal horn neurons to 5-HT compared with scratching. (a) Averaged peristimulus–time histogram (PSTH, bin width: 1 s) of responses of superficial dorsal horn neurons to intradermal microinjection of 5-HT (60 mM; 1 μl) at arrow in pentobarbital-anesthetized rats. Inset shows recordings sites (dots) compiled on section through L5 dorsal horn. (b) Graph plots mean number of hindlimb scratching bouts (error bars: SEM) directed toward the site of injection of 5-HT in the nape of the neck in Sprague-Dawley rats. Scratching bouts were counted in 2 min intervals. Adapted from Jinks, S. L. and Carstens, E. 2002. Prolonged responses of superficial dorsal horn neurons to intracutaneous serotonin and other irritant chemicals: comparison with scratching behavior. J. Neurophysiol. 87, 1280–1289.

pruriceptors is suggested by microneurographic recordings from an atopic dermatitis patient, revealing a subset of mechanically insensitive C-fiber afferents that exhibited irregular patterns of spontaneous activity; two of these were activated by pruritic stimulation (Schmelz, M. *et al.*, 2003a). Since mechanically insensitive, histamine-responsive C-fibers normally do not exhibit any spontaneous activity (Schmelz, M. *et al.*, 1997), their increased firing in atopic dermatitis may represent sensitization that contributes to spontaneous itch. Central sensitization is also likely to contribute to pathological itch (Ikoma, A. *et al.*, 2004). Central sensitization of pain is mediated partly via excessive excitation of spinal neurons by nociceptors releasing glutamate and SP, which act at postsynaptic NMDA and neurokinin-1 receptors to initiate Ca^{2+}-dependent intracellular events resulting in enhanced neuronal excitability (Ji, R. R. *et al.*, 2003). Central sensitization is associated with hyperalgesia (increased pain), allodynia (pain from a normally nonpainful stimulus), and expansion of mechanosensitive receptive fields. It is conceivable that conditions associated with chronic itch may induce central sensitization of itch-signaling neurons via mechanisms similar to those for central sensitization of pain (Ikoma, A. *et al.*, 2004).

5.09.6 Central Representation of Itch

Using positron emission tomography (PET), histamine injection in the right upper arm differentially activated the contralateral anterior cingulate cortex, ipsilateral inferior parietal lobule, as well as bilateral supplementary and premotor cortical areas (Hsieh, J. C. *et al.*, 1994). Activation of the ipsilateral premotor cortical areas was suggested to represent an urge to scratch. A more recent PET study using histamine pin prick on the right arm reported dose-related activation in premotor and supplementary motor areas and anterior cingulate gyrus, as well as in contralateral primary (but not secondary) somatosensory and primary motor cortex, prefrontal cortex and contralateral insula, and prefrontal and superior temporal cortex (Drzezga, A. *et al.*, 2001). While there was some overlap in cortical areas activated by itch versus pain, there were notable differences, particularly in the activation of secondary somatosensory cortex and thalamus by pain but not itch (Drzezga, A. *et al.*, 2001). A third recent PET study also reported dose-related activation in many of the same cortical areas by iontophoretically applied histamine, but notably also in thalamus. Simultaneous application of a noxious cold (5 °C) stimulus reduced the degree of histamine-evoked cortical activation. Interestingly, coapplication of noxious cold and histamine revealed significant activation in midbrain periaqueductal gray (PAG). This suggests that in addition to the well-known role of the PAG in pain modulation, it may also play a role in modulation of itch (Carstens, E., 1997; Mochizuki, H. *et al.*, 2003). These studies indicate that noxious and pruritic stimuli activate overlapping as well as separate cortical and subcortical regions, lending partial support for separate central pathways mediating itch versus pain.

5.09.7 Animal Models of Itch

Scratching directed toward a site of pruritic stimulation in rodents is thought to reflect itch sensation (Berendsen, H. H. G. and Broekkamp, C. L. E., 1991; Kuraishi, Y. *et al.*, 1995). However, scratching is a normal grooming behavior and in some cases may reflect pain rather than itch (DeCastro-Costa, M. *et al.*, 1987). Moreover, hindlimb scratching is elicited by intrathecal injection of numerous agents including neurokinins, capsaicin, and morphine (Frenk, H. *et al.*, 1988; Wilcox, G. L., 1988; Ko, M. C. and Naughton, N. N., 2000), even in spinalized animals (Bossut, D. *et al.*, 1988) suggesting direct activation of motor scratch reflex circuits. Facial scratching is also elicited by intracerebroventricular and intramedullary injection of opiates (Königstein, H., 1948; Thomas, D. A. *et al.*, 1993; Thomas, D. A. and Hammond, D. L., 1995; Tohda, C. *et al.*, 1997b; Johnson, M. D. *et al.*, 1999; Kuraishi, Y. *et al.*, 2000) and other substances including adrenocorticotropic hormone (ACTH) and many neuropeptides (Share, N. N. and Rackham, A., 1981; Van Wimersma Greidanus, T. B., 1986; Van Wimersma Greidanus, T. B. *et al.*, 1987; Van Wimersma Greidanus, T. B. and Maigret, C., 1988; Van Wimersma Greidanus, T. B. *et al.*, 1988; Van Wimersma Greidanus, T. B. and Maigret, C., 1991; Johnson, M. D. *et al.*, 1999).

Despite the caveats noted above, there is good evidence that hindlimb scratching may distinguish between itch and pain. Substances that induce itch in humans, including SP (Hagermark, O. *et al.*, 1978), the mast cell degranulator compound 48/80 (Fjellner, B. and Hägermark, O., 1982), serotonin (5-HT; Weisshaar, E. *et al.*, 1997), and platelet activating factor (PAF, Fjellner, B. and Hägermark, O., 1985), elicit dose-related scratching in rodents (Berendsen, H. H. G and Broekkamp, C. L. E, 1991; Kuraishi, Y. *et al.*, 1995;

Woodward, D. F. *et al.*, 1995; Yamaguchi, T. *et al.*, 1999; Thomsen J. S. *et al.*, 2001; Jinks, S. L. and Carstens, E., 2002). In contrast, capsaicin and formalin, which induce burning pain, elicit little or no scratching (Kuraishi, Y. *et al.*, 1995; Yamaguchi, T. *et al.*, 1999; Jinks, S. L. and Carstens, E., 2002). One notable difference is histamine, which is the definitive pruritogen in humans (Simone, D. A. *et al.*, 1987; 1991; Hagermark, O., 1995) yet does not elicit scratching in several strains of mice (Kuraishi, Y. *et al.*, 1995; Yamaguchi, T. *et al.*, 1999; Inagaki, N. *et al.*, 2001) or Sprague-Dawley rats (Thomsen, J. S. *et al.*, 2001; Jinks, S. L. and Carstens, E., 2002). This might be explained by the much lower concentration of histamine in cutaneous mast cells of rodents (Gustafsson, B., 1980; Graziano, F. M., 1988; Purcell, W. M. *et al.*, 1989) in favor of 5-HT which induces scratching via the 5-HT_2 receptor (Yamaguchi, T. *et al.*, 1999; Nojima, H. and Carstens, E., 2003b). However, other rodent strains including the ICR mouse (Maekawa, T. *et al.*, 2000) and hairless guinea-pig (Woodward, D. F. *et al.*, 1995) exhibit dose-related scratching to histamine, indicating the existence of strain differences in the scratch-inducing potency of itch mediators.

Importantly, opiate antagonists significantly attenuated hindlimb scratching elicited by 5-HT (Yamaguchi, T. *et al.*, 1999; Nojima, H. and Carstens, E., 2003a; Nojima, H. *et al.*, 2003b) or SP (Andoh, T. *et al.*, 1998). This is consistent with the report that opiate antagonists reduce histamine-induced itch in humans (Heyer, G. *et al.*, 1997a) and further supports scratching as an itch-related response.

Additional animal models of acute itch include hindlimb scratching directed toward the eye in albino guinea-pigs (Woodward, D. F. *et al.*, 1995). In this model, histamine, 5-HT, PAF, and prostaglandin E_2 elicited significant, dose-related ocular scratching while even high concentrations of the algesic agents bradykinin, acetic acid, or saline did not. Another model is biting directed toward the site of 5-HT injected into the hind paw of mice (Hagiwara, K. *et al.*, 1999). 5-HT (60–100 nmol) elicited approximately equal numbers of licks and bites, but only biting was significantly attenuated by both naloxone and the 5-HT antagonist, methysergide. In contrast, formalin elicited hind paw licking but no biting. These results suggest that biting represents a means of noxious counterstimulation of the paw to relieve itch.

Animal models of acute allergic (e.g., Inagaki, N. *et al.*, 2000; Ohtsuka, E. *et al.*, 2001; Nojima, H. and Carstens, E., 2003b) and dry-skin itch (Miyamoto, T. *et al.*, 2002b; Nojima, H. *et al.*, 2003a; Nojima, H. *et al.*, 2004) have also been developed. One model that most people can relate to is mosquito-bite-induced itch. Initial exposure of ICR mice to mosquito bites did not result in scratching. However, twice-weekly exposure of the mice to mosquito bites resulted in a progressive increase in scratching. Naïve mice sensitized by injection of female mosquito salivary gland extract (the presumed antigen) exhibited marked scratching upon the first mosquito bite, indicating that it triggered an acute allergic reaction and associated itch (Ohtskua, E. *et al.*, 2001).

A potential model of chronic itch is the NC/jic mouse (Tohda, C. *et al.*, 1997a; Yamaguchi, T. *et al.*, 2001). Within 2–6 months after birth, a majority of these animals spontaneously develop skin lesions (eczema, bleeding, alopecia) associated with excessive scratching that is naloxone-sensitive. These animals did not develop skin lesions, scratching, or increased plasma immonoglobulin G levels when reared in a specific pathogen-free environment, but did so within 4 weeks after being transferred to a conventional environment. The NC/jic mouse may represent an animal model of itch associated with chronic dermatitis, affording the possibility to develop novel antipruritic treatment strategies for clinical cases of itch that are poorly treated by antihistamines.

5.09.8 Itch Mediators

Histamine is the most important mediator of normal human itch. It is localized in cutaneous mast cells along with a variety of other chemicals including serotonin, chymase, and tryptase. Intradermal histamine primarily elicits a dose-dependent sensation of itch (Melton, F. M. and Shelly, W. P., 1950; Keele, C. A. and Armstrong, D., 1964; Handwerker, H. O. *et al.* 1987; Simone, D. A. *et al.* 1987; 1991). Microdialysis of histamine in the skin elicited almost exclusively, itch sensation and strongly excited mechanically insensitive C-fibers that are considered to be pruriceptors as discussed earlier (Schmelz, M. *et al.*, 2003b). The itch sensation evoked by histamine and other pruritic chemicals (e.g., serotonin, SP, PAF, vasoactive intestinal polypeptide) is in nearly all cases prevented by pretreatment with H_1 receptor antagonists (Hagermark, O., 1992; Heyer, G. and Magerl, W., 1995), suggesting a common action via histamine released by mast cell degranulation. However, other mediators might act independently of histamine release to induce itch, as discussed further below.

More than 50 years ago, Arthur R. P. and Shelley W. B. (1955) reported the itch-inducing effects of proteases including mucunain (Shelley W. B. and Arthur, R. P., 1955), a peptidase extracted from spicules of the velvet bean plant, cowhage, which elicit itch upon contact with skin. The serine proteases trypsin and chymase and the cystein protease papain induce itch that may be independent of histamine (Rajka, G., 1969; Hagermark, O. *et al.*, 1972). Mast cell chymase elicited scratching in mice, and a chymase inhibitor reduced allergic scratching (Imada, T. *et al.*, 2002). An exciting new development is the discovery of the proteinase-activated receptor (PAR). One subtype, PAR-2, is targeted by trypsin and mast cell tryptase, is expressed in sensory neurons and other tissues (Steinhoff, M. and Roosterman, D., 2005) and may be involved in itch (Steinhoff, M. *et al.*, 2003). In particular, PAR-2 expression is increased fourfold in patients with atopic dermatitis, and these patients experience itch upon intralesional application of PAR-2 agonists that is histamine-independent (Steinhoff, M. *et al.*, 2003). Thus, PAR-2 represents a novel target for antipruritic drugs, particularly for conditions like atopic dermatitis in which the itch is refractory to antihistamines.

Serotonin (5-HT) delivered to the skin induces weak itch in humans (Hagermark, O., 1992; Weisshaar, E. *et al.*, 1997) and may be involved in the pruritus of polycythemia vera (Fjellner, B. and Hagermark, O., 1979; Fitzsimons, E. J. *et al.*, 1981) and cholestasis (Schworer, H. *et al.*, 1995; Weisshaar, E. *et al.*, 1999; Jones, E. A. and Bergasa, N. V., 2000). Intradermal microdialysis of 5-HT elicited weak-to-moderate itch in some subjects and pain in others, but excited mechanically insensitive, histamine-sensitive C-fiber pruriceptors (Schmelz, M. *et al.*, 2000b; 2003a) in support of a role as itch mediator. As noted earlier, 5-HT potently induces scratching in rodents via the 5-HT_2 receptor (Yamaguchi, T. *et al.*, 1999; Nojima, H. and Carstens, E., 2003b), whereas the 5-HT_3 receptor may be involved under certain chronic itch conditions in humans (Schworer, H. *et al.*, 1995; Weisshaar, E. *et al.*, 1999).

Intradermal injection (Hagermark, O. and Strandberg, K., 1977) or microdialysis (Neisius, U. *et al.*, 2002; Schmelz, M. *et al.*, 2003) of prostaglandin E_2 also elicited weak itch in some subjects and strongly excited histamine-sensitive C-fiber pruriceptors (Schmelz, M. *et al.*, 2003).

Acetylcholine normally elicits pain, but instead induced itch in patients with atopic dermatitis (Heyer, G. *et al.*, 1997b). Intradermal microdialysis of acetylcholine induced itch in some subjects but more frequently pain, and excited most histamine-sensitive C-fiber pruriceptors tested (Schmelz, M. *et al.*, 2003). Cholinergic agonists elicited dose-related scratching in mice that was reduced by opiate and muscarinic M3 receptor antagonists; nicotine did not elicit scratching (Miyamoto,T. *et al.*, 2002).

Intradermal injection of the neuropeptide SP elicits itch (Hagermark, O. *et al.*, 1978; Thomsen, D. A. *et al.*, 2002) via mast cell degranulation (Hagermark, O. *et al.*, 1978). However, a recent study reported no itch or pain sensations with up to 10^{-5} M SP delivered by intradermal microdialysis, and concluded that physiological levels of SP are insufficient to induce mast cell degranulation (Weidner, C. *et al.*, 2000). In rodents, SP elicited dose-dependent scratching that was reduced by opiate and neurokinin-1 antagonists, and was at least partly independent of mast cell degranulation (Andoh, T. *et al.*, 1998).

A variety of other mediators may also have some role in itch. PAF elicits histamine-dependent itch in humans (Fjellner, B. and Hagermark, O., 1985), and scratching behavior in guinea-pigs, which, however, was reduced by PAF antagonists but not by histamine H1 antagonists (Woodward, D. F. *et al.*, 1995). Leukotriene B_4 (LTB_4) elicited scratching in mice that was attenuated by an LTB_4 antagonist (Andoh, T. and Kuraishi, Y., 1998). LTB_4 also plays a role in scratching elicited by intradermal injection of SP (Andoh, T. *et al.*, 2001) and nociceptin (Andoh, T. *et al.*, 2004). Endothelin delivered by intradermal microdialysis or injection induced short-lasting burning itch accompanied by release of histamine and nitric oxide (Wenzel, R. R *et al.*, 1998; Katugampola, R. *et al.*, 2000). Interleukin-2 (IL-2), but not tumor necrosis factor-alpha, given intradermally induced weak itch (Wahlgren, C. F. *et al.*, 1995; Darsow, U. *et al.*, 1997) and there is indirect evidence that IL-4 and IL-6 may also have some role in pathological itch (Nordlind, K. *et al.*, 1996; Chan, L. S. *et al.*, 2001).

The preceding list is by no means comprehensive, but certainly we have now at least scratched the surface in terms of identifying peripheral mediators, receptors, and neural pathways involved in signaling the enigmatic sensory quality of itch.

5.10.1 Introduction

We feel a wide range of temperatures spanning from cold to heat. Within this range, temperatures over about 43 °C and below about 15 °C evoke not only a thermal sensation, but also a feeling of pain. The neurons that allow us to sense temperatures are located in the dorsal root ganglia (DRG) and within cranial nerve ganglia such as trigeminal ganglion (TG). It has been hypothesized that cutaneous nociceptor endings detect temperature and other physical stimuli by means of ion channels responsive to these stimuli. Insight into the molecular nature of the temperature-activated channels came with the cloning of the capsaicin receptor, TRPV1 (Caterina, M. J. *et al.*, 1997). TRPV1 is a member of the TRP (transient receptor potential) superfamily of ion channels, whose prototypical member, TRP, was found to be deficient in a *Drosophila* mutant exhibiting abnormal responsiveness to continuous light (Montell, C., 2005). Three other TRPV channels, TRPV2, TRPV3, and TRPV4, have been cloned and characterized as heat thermosensors (Jordt, S. E. *et al.*, 2003; Patapoutian, A. *et al.*, 2003). The threshold temperatures for activation of these channels range from relatively warm (TRPV3 and TRPV4) to extremely hot (TRPV2). In contrast to the four thermosensitive TRPV channels, two other TRP channels, TRPM8 and TRPA1, have been found to be activated by cold stimuli (Jordt, S. E. *et al.*, 2003; Patapoutian, A. *et al.*, 2003). Between the two channels, TRPA1 is perhaps more likely to be involved in nociception because the temperature threshold for its activation is about 17 °C, close to the reported threshold for cold nociceptors.

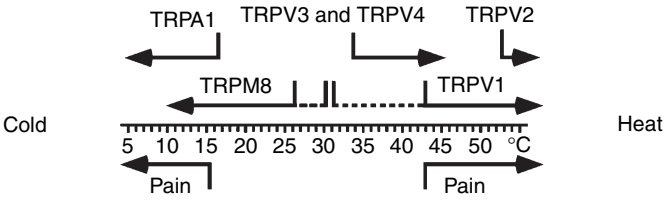
5.10.2 Heat Receptors

5.10.2.1 TRPV1 (VR1)

5.10.2.1.1 Cloning of TRPV1 and its characterization

One characteristic shared by many nociceptive neurons is sensitivity to capsaicin, the main pungent ingredient of hot chili peppers (Szallasi, A. and Blumberg, P. M., 1999). A capsaicin receptor was isolated in 1997 and designated vanilloid receptor subtype 1 (VR1) (Caterina, M. J. *et al.*, 1997), and now it is called TRPV1 in TRPV subfamily of a large TRP ion channel superfamily (Figure 1). Patch-clamp recordings (Caterina, M. J. *et al.*, 1997; Tominaga, M. *et al.*, 1998) revealed that TRPV1 is a nonselective cation channel with high Ca^{2+} permeability and that TRPV1 can be activated not only by capsaicin but also by protons and heat over 43 °C, all of which are known to cause pain *in vivo*. Single channel openings of TRPV1 by any of the three

(a)



(b)

Receptor	Temperature threshold for activation	Expression	Other effective stimuli
TRPV1	>43 °C	Sensory neurons brain/ skin?	Capsaicin/ proton lipids 2-Aminoethoxydiphenyl borate (2APB)
TRPV2	>52 °C	Sensory neurons/ brain/ spinal cord/ lung/ liver/ spleen/ colon	Mechanical stimulus 2-Aminoethoxydiphenyl borate (2APB)
TRPV3	>32–39 °C	Sensory neurons/ brain/ spinal cord/ skin/ stomach/ colon	2-Aminoethoxydiphenyl borate (2APB) camphor
TRPV4	>27–35 °C	Sensory neurons/ hypothalamus/ skin/ kidney/ lung/ inner ear	Hypotonic stimulus/ 4αPDD Mechanical stimulus Epoxyeicosatrienoic acids
TRPM8	<25–28 °C	Sensory neurons	Menthol/ icilin
TRPA1	<17 °C	Sensory neurons	Allyl isothiocyanate Δ^9-tetrahydrocannabinol cinnamaldehyde mechanical stimulus

Figure 1 (a) Temperatures causing pain and activating six thermosensitive transient receptor potential (TRP) channels. Dotted lines indicate that threshold temperatures for activation of TRPV1 and TRPM8 are not fixed but changeable in the presence of other stimuli (see text). (b) Comparison of the mammalian six thermosensitive TRP channels.

stimuli in a membrane-delimited fashion indicate that the three stimuli gate TRPV1 directly and that TRPV1 is, itself, a heat sensor. These stimuli are likely to work in concert to regulate the activity of TRPV1 *in vivo*, especially under pathological conditions where tissue acidosis and elevated temperature may come into play. TRPV1 transcript and protein were found to be most highly expressed in sensory neurons (Caterina, M. J. *et al.*, 1997; Tominaga, M. *et al.*, 1998). Moreover, *in situ* hybridization and immunostaining revealed that, within DRG and TG, TRPV1 expression predominated in small-diameter cell bodies, most of which give rise to unmyelinated C fibers.

To determine whether TRPV1 really contributes to the detection of these noxious stimuli *in vivo*, mice lacking this protein were generated and analyzed for nociceptive function. Sensory neurons from mice lacking TRPV1 were deficient in their responses to each of the reported noxious stimuli – capsaicin, proton, and heat (Caterina, M. J. *et al.*, 2000). Consistent with this observation, behavioral responses to capsaicin were absent, and responses to acute thermal stimuli were diminished in these mice. The most prominent feature of the knockout mouse thermosensory phenotype was a virtual absence of thermal hypersensitivity in the setting of inflammation. These findings indicate that TRPV1 is essential for selective modalities of pain sensation and for tissue injury-induced thermal hyperalgesia.

5.10.2.1.2 Reduction of temperature threshold for TRPV1 activation: A mechanism for inflammatory pain

Inflammatory pain is characterized by hypersensitivity both at the site of damage and in the adjacent tissue, and one underlying mechanism is the modulation (sensitization) of ion channels such as TRPV1. Sensitization is triggered by extracellular inflammatory mediators that are released *in vivo* from surrounding damaged or inflamed tissues and from nociceptive neurons themselves (Julius, D. and Basbaum, A. I., 2001). Tissue acidification is also induced in pathological conditions such as ischemia or inflammation, and such acidification exacerbates or causes pain. Among the inflammatory mediators, extracellular ATP, bradykinin, prostaglandins (PGE_2 and PGI_2), or tryptase or trypsin have been reported to potentiate TRPV1 responses through their

Gq-coupled $P2Y_2$, B_2, EP_1, IP, or PAR2 (proteinase activated receptor 2) receptors, respectively, mainly in a protein kinase C (PKC)-dependent manner in both a heterologous expression system and native DRG neurons (Tominaga, M. and Caterina, M. J., 2004; Moriyama, T. *et al.*, 2005). In addition to potentiating capsaicin- or proton-evoked currents, in the presence of the inflammatory mediators, the threshold temperature for heat activation of TRPV1 was reduced to as low as 30 °C, such that normally nonpainful thermal stimuli (i.e., normal body temperature) are capable of activating TRPV1. Under these circumstances, the inflammatory mediators seem to act as direct activators of TRPV1. This represents a novel mechanism through which the large amounts of the mediators released from different cells in inflammation might trigger a sensation of pain. Interactions between the Gq-coupled receptors and TRPV1 in relation to inflammatory pain have been proven at behavioral level using the Gq-coupled receptor- or TRPV1-deficient mice (Tominaga, M. and Caterina, M. J., 2004; Moriyama, T. *et al.*, 2005). A PKA-dependent and PIP_2-mediated pathways also seem to be involved in TRPV1 sensitization (Tominaga, M. and Caterina, M. J., 2004).

Tissue acidification is induced in pathological conditions such as ischemia or inflammation, and such acidification exacerbates or causes pain. In addition to the direct activation of TRPV1, acidification also shifts temperature–response curve of TRPV1 to the left so that the channel can be activated at lower temperatures (lower than body temperature) and responses to heat are bigger at a given suprathreshold temperature (Tominaga, M. *et al.*, 1998). This phenomenon might also contribute to inflammatory pain.

5.10.2.2 TRPV2 (VRL-1)

A protein, which is 49% identical to TRPV1, was isolated and designated VRL-1 and later renamed TRPV2 (Caterina, M. J. *et al.*, 1999; Jordt, S. E. *et al.*, 2003; Patapoutian, A. *et al.*, 2003; Tominaga, M. and Caterina, M. J., 2004) (Figure 1). TRPV2 can be activated by high temperatures with a threshold of ~52 °C. TRPV2 currents showed similar properties to those of TRPV1 such as high Ca^{2+} permeability.

Intense TRPV2 immunoreactivity was observed in medium- to large-diameter cells in rat DRG neurons (Caterina, M. J. *et al.*, 1999). Together with the fact that many of the TRPV2 immunoreactive cells in rat DRG costained with the marker for myelinated neurons, it was concluded that TRPV2 is preferentially expressed in Aδ fibers. TRPV2 transcript and protein were found not only in sensory neurons but also in motoneurons and in many nonneuronal tissues that are unlikely to be exposed to temperatures above 50 °C (Caterina, M. J. *et al.*, 1999). These results indicate that TRPV2 undoubtedly contributes to numerous functions in addition to nociceptive processing.

5.10.2.3 TRPV3 and TRPV4

TRPV3 and TRPV4 have been found to be activated by warm temperatures, ~34–38 °C for TRPV3 and ~27–35 °C for TRPV4, in heterologous expression systems and mouse keratinocytes, and to be expressed in multiple tissues, including, among others, sensory and hypothalamic neurons and keratinocytes (Jordt, S. E. *et al.*, 2003; Patapoutian, A. *et al.*, 2003; Tominaga, M. and Caterina, M. J., 2004) (Figure 1). Among the tissues, both TRPV3 and TRPV4 were most predominantly expressed in the skin keratinocytes and have been reported to be involved in thermosenation by keratinocytes, based on the studies using wildtype and TRPV3- or TRPV4-deficient keratinocytes (Chung, M. K. *et al.*, 2004; Lee, H. *et al.*, 2005; Moqrich, A. *et al.*, 2005). Thermosensing ability of TRPV3 or TRPV4 were proven at animal level because both TRPV3- and TRPV4-deficient mice exhibited some different thermal preference from that in wildtype mice. TRPV4 has also been shown to be involved in mechanical stimulus- and hypotonicity-induced nociception in rodents at baseline or following hypersensitivity induced by prostaglandin injection or taxol hypersensitivity. Furthermore, TRPV4-deficient mice reportedly exhibit deficits in inflammation-induced thermal hyperalgesia (Todaka, H. *et al.*, 2004). TRPV3 has been reported to function as a camphor receptor (Moqrich, A. *et al.*, 2005).

5.10.3 Cold Receptors

5.10.3.1 TRPM8

The cooling sensation of menthol, a chemical agent found in mint, is well established, and both cooling and menthol have been suggested to be transduced through a nonselective cation channel in DRG neurons (Figure 1). Two groups independently cloned and characterized a cold receptor, TRPM8, which can be also activated by menthol (McKemy, D. D.

et al., 2002; Peier, A. M. *et al.*, 2002). In heterologous expression systems, TRPM8 could be activated by menthol or by cooling, with an activation temperature of ~25–28 °C. TRPM8 could alternatively be activated by other cooling compounds, such as menthone, eucalyptol, and icilin. There also appears to be interaction between effective stimuli for TRPM8, in that subthreshold concentrations of menthol increased the temperature threshold for TRPM8 activation from 25 °C to 30 °C. This is reminiscent of TRPV1, whose activation temperature is reduced under mildly acidic conditions that do not open TRPV1 alone (Tominaga, M. *et al.*, 1998). Whole-cell recording in HEK293 cells expressing TRPM8 revealed that TRPM8 is a nonselective cation channel with relatively high Ca^{2+} permeability.

TRPM8 is expressed in a subset of DRG and TG neurons that can be classified as small-diameter C fiber-containing neurons (McKemy, D. D. *et al.*, 2002; Peier, A. M. *et al.*, 2002). Interestingly, however, TRPM8 is not coexpressed with TRPV1.

5.10.3.2 TRPA1

TRPA1 was reported as a distantly related TRP channel which is activated by cold with a lower activation threshold as compared with TRPM8 (Story, G. M. *et al.*, 2003) (Figure 1). In heterologous expression systems, TRPA1 was activated by cold stimuli with an activation temperature of about 17 °C, which is close to the reported noxious cold threshold. This finding led to the suggestion that TRPA1 is involved in cold nociception. Whole-cell recording in Chinese hamster ovary (CHO) cells expressing TRPA1 revealed cationic permeability with similar preferences for monovalent and divalent cations. Whether TRPA1 is gated directly by cold remains to be elucidated. A study from another group failed to reproduce cold responsiveness in TRPA1 (Jordt, S. E. *et al.*, 2004). The reason for this apparent discrepancy is unclear. However, both groups have demonstrated that TRPA1 can be activated by pungent isothiocyanate compounds such as those found in wasabi, horseradish, cinammon, and mustard oil (Tominaga, M. and Caterina, M. J., 2004). Thus, several of the thermosensitive TRP channels likely to be involved in nociception can be activated by stimuli other than temperature.

Unlike TRPM8, TRPA1 is specifically expressed in a subset of sensory neurons that express the nociceptive markers CGRP and substance P (Story, G. M. *et al.*, 2003). Furthermore, TRPA1 is frequently coexpressed with TRPV1, raising the possibility that TRPA1 and TRPV1 mediate the function of a class of polymodal nociceptors. Such coexpression might also explain the paradoxical hot sensation experienced when one is exposed to a very cold stimulus.

5.10.4 Thermonociception by Non-TRP Proteins

The discovery of thermosensitive TRP channels indicates that thermosensation is mediated in part by a common molecular mechanism involving ion channels such as TRP channels as primary transducers of thermal stimuli. However, it is still possible that other proteins are involved in thermosensation and thermonociception. Indeed, TREK-1, a member of a family of mammalian two-pore domain K^+ channels, is expressed in mouse DRG neurons and activated by heat. Because opening of TREK-1 causes hyperpolarization of the membrane potential by efflux of K^+ ions, TREK-1 might be involved in pain relief through the reduction of firing upon noxious heat stimulus. Alternatively, inhibition of TREK-1 by cold stimuli might lead to nociception through depolarization. Further studies will be necessary to determine whether TREK-1 is involved in thermonociception. In addition to K^+ channels, other membrane proteins such as Na^+/K^+ ATPase, members of degenerin/epithelial sodium channels (DEG/ENaC), and $P2X_3$ receptors have been reported to be thermosensative. However, the involvement of those proteins in thermonociception remains to be established.

5.10.5 Conclusion

Significant advances in thermonociception research have been made in the last several years with the cloning and characterization of thermosensitive TRP channels. It is not known how multiple thermosensitive TRP channels are used within the same or different sensory neurons to provide us with the ability to evaluate temperature precisely over a broad range. Central integration of the thermal information acquired by peripheral nerve endings is almost certainly a critical component of this process. Furthermore, regulatory mechanisms similar to those emerging for TRPV1 are likely to exist for most of the thermosensitive TRP channels. Therefore, an

understanding of the molecules surrounding thermosensitive TRP channels from the periphery to the central nervous system will be indispensable to a complete understanding of thermonociception.

Glossary

A fibers Large-diameter myelinated primary afferent sensory fibers with large cell bodies in the dorsal root ganglion. The largest diameter Aβ fibers are mainly low-threshold mechanoceptors and the smaller Aδ fibers are both mechanoreceptors and nociceptors.

C fibers Small-diameter unmyelinated primary afferent sensory fibers with small cell bodies in the dorsal root ganglion. The majority are nociceptors. They divide into a neuropeptide containing, Trk-receptor expressing group and a lectin IB4 binding group although the functional implications of this are still unclear.

embryonic (E) age These are dated from the time of fertilization. Rat gestation is 21.5 days, mouse a little shorter. Rats are born relatively early in terms of CNS development and the early postnatal period is often paralleled with the final gestation of development in man.

receptive field The area on the body surface that when stimulated evokes action potentials in a given neuron.

periaqueductal gray An area of the brainstem that surrounds the aqueduct connecting the third and fourth ventricles. This area projects to the medullary raphe region, which in turn sends projections down the dorsolateral funiculus of the spinal cord to the dorsal horn. This pathway is known to strongly modulate spinal pain processing.

receptor subunits Ion channels are generally made up of several glycoprotein subunits around a central pore. These subunits can confer special characteristics upon a channel, such as increased calcium permeability or longer opening times. The subunits of many channels change with development, thereby altering the channel properties.

5.11.1 The Development of Nociceptors and Their Peripheral and Spinal Connections

Pain is usually, although not always, triggered by tissue damage and consequently a discussion of developing nociceptive pathways begins with the maturation of primary sensory neurons in the dorsal root ganglia (DRG) and their peripheral and central connections. The two main subtypes of primary sensory neurons, A cells and C cells (future nociceptors) are specified at an early stage of development under the control of specific transcription factors. In the rat, lumbar DRG cells are born in two waves from embryonic day (E)12–E15 (gestation 21.5 days); C cells are born in the second wave, later than the larger-diameter A cells. There is evidence also that the future peptidergic nociceptors are born before the nonpeptidergic group (Hall, A. K.

et al., 1997; Jackman, A. and Fitzgerald, M., 2000). Young C cells immediately send out centrally and peripherally directed processes, again lagging some days behind A cells. However, from the time that they innervate peripheral skin, nociceptors are capable of transmitting information about noxious cutaneous stimulation (Box 1).

The study of sensory neurogenesis, axon outgrowth, and target finding is a fast-moving and exciting area of developmental biology. Not only are there a number of key regulatory genes controlling these events but the many aspects of nociceptor development are dependent upon access to neurotrophic factors (Fitzgerald, M., 2005). A key neurotrophic factor affecting nociceptor development is nerve growth factor, NGF, which not only determines nociceptor fate but is also critically required for nociceptor survival (Davies, A. M., 2000; Fitzgerald, M., 2005) during embryonic life and continues to influence nociceptor development postnatally by

1. NGF regulates axon outgrowth, independently of cell survival (Markus, A. *et al.*, 2002).
2. NGF determines nociceptor physiological properties. NGF signaling in the early postnatal period is required for C nociceptors to respond to noxious heat and for the normal development of myelinated high-threshold mechanoreceptors (Aδ fibers) (Ritter, A. M. *et al.*, 1991; Lewin, G. R. and Mendell, L. M., 1994).
3. NGF influences nociceptor expression of the neuropeptides substance P (SP) and calcitonin-gene-related peptide (CGRP) (Davies, A. M., 2000; Hall, A. K. *et al.*, 2001).
4. NGF regulates skin innervation density. Excess epidermal NGF leads to hyperinnervation (Davis, B. M. *et al.*, 1997).

The growth of C-fiber terminals into the spinal dorsal horn occurs just before birth in the rat and from the outset, these fibers terminate in a somatotopically precise manner in laminae I–II of the dorsal horn. Neuropeptide containing nocieptive terminals in laminae I and II can be detected prenatally, steadily increasing in density over the first 10 postnatal days, while IB4+ve terminals appear a few days later, suggesting that these fibers may form central connections later than peptidergic fibers and indeed be involved in a separate central pain pathway (Braz, J. M. *et al.*, 2005).

The immature C-fiber terminals are functional at birth but neurotransmitter release is of low frequency and the synapses are too immature to evoke substantial spike activity *in vivo* until the second postnatal week. This in contrast to the A fiber which, when stimulated, can evoke robust action potentials in dorsal horn cells from before birth (Fitzgerald, M. and Jennings, E., 1999; Baccei, M. L. *et al.*, 2003). As in the adult, immature C fibers terminate exclusively in laminae I and II. However, in the first postnatal weeks, they share this termination area with large-diameter Aβ afferents whose terminals extend dorsally into laminae II and I and form transient synaptic connections. This is followed by a gradual withdrawal from the superficial laminae over the first 3 postnatal weeks (Fitzgerald, M. *et al.*, 1994). The postnatal withdrawal of Aβ fibers from the superficial dorsal horn is an activity-dependent process, which that can be prevented by intrathecal application of the NMDA receptor antagonist MK801 (Beggs, S. *et al.*, 2002). The functional implications of the presence of A fibers in newborn lamina II are not known but they may contribute to the larger receptive fields and increased excitability to tactile stimulation described below.

Box 1 Postnatal development of C nociceptor properties

Although all of the broad functional classes of primary afferents are present in the rat hindlimb at birth, the maturation process varies according to the individual stimulus modality (Koltzenburg, M., 1999). From birth, polymodal nociceptors respond to noxious chemical, mechanical, and thermal stimuli with thresholds and firing frequencies that are characteristic of mature C fibers (Fitzgerald, M., 1987; Keller, A. F. *et al.*, 2004). This is consistent with early expression of TRPV1, critical for the detection of painful thermal and chemical stimuli, and the ATP-gated $P2X_3$ receptor (Guo, A. *et al.*, 2001) that plays an important role in thermal and mechanical hyperalgesia following inflammation or nerve injury and the tetrodotoxin-resistant sodium channel Nav1.8, necessary for the normal detection of noxious mechanical and thermal stimuli and the sensitization of nociceptive sensory neurons (Benn, S. C. *et al.*, 2001).

Nociceptive cells require activation of trkA receptors by nerve growth factor (NGF) for survival during the embryonic period, but during the postnatal period, a subset of these neurons downregulate trkA and become dependent on glial-cell-line-derived neurotrophic factor (GDNF) via the expression of the GDNF receptor Ret (Bennett, D. L. *et al.*, 1996; Molliver, D. C. *et al.*, 1997). Thus the clear distinction between (1) the trkA+ve, neuropeptide containing C fibers and (2) the IB4+ve, nonpeptidergic nociceptors appears postnatally, although the functional implications of this in terms of nociception is not clear.

5.11.2 The Development of Spinal Nociceptive Circuits

At birth, strong spinal nociceptive reflexes can be evoked by mechanical stimulation, which are exaggerated compared to the adult for the first 2–3 postnatal weeks (Ekholm, J., 1967; Fitzgerald, M. *et al.*, 1988) with lower thresholds and larger, more synchronized and prolonged muscle contractions. A prick on the hind foot in the newborn rat can evoke limb withdrawal, wriggling, rolling, and simultaneous responses from all four limbs. Receptive fields of hindlimb flexor muscles are large and disorganized such that the limb withdrawal can be evoked that is not always appropriate to the stimulus (Holmberg, H. and Schouenborg, J., 1996). As the pup matures, the response decreases in magnitude and becomes restricted to an isolated leg or foot movement. Thresholds for withdrawal from heat stimuli are also lower in younger animals. In contrast with mechanical reflexes, but consistent with the slow synaptic maturation of C-fiber-evoked responses, cutaneous application of the selective C-fiber irritant, mustard oil, evokes little or no spinal reflex response until postnatal day 10 (Baccei, M. L. and Fitzgerald, M., 2005).

The excitability of mechanical neonatal cutaneous reflexes is attributable to underlying changes in dorsal horn sensory processing and is likely to be due to absence of fine-tuning of sensory and nociceptive neuronal circuitry in the newborn. The earlier maturation and widespread presence of functional A-fiber terminals in both the substantia gelatinosa and deeper laminae in the first weeks of life appear to adequately compensate for the weak C-fiber input and dominate the physiological responses of dorsal horn neurons, fewer of which are nociceptive in the newborn cord, especially of the wide dynamic range (WDR) variety. Receptive field areas of dorsal horn cells, mapped by natural mechanical stimulation of skin, are large at birth and decrease in size with age. Pinching or brushing the receptive field of many neonatal dorsal horn cells results in long-lasting after-discharges (30–90 s) which on days 0–3 may be more pronounced than the initial evoked response but which decrease in duration and amplitude of these responses with age (Fitzgerald, M. and Jennings, E., 1999; Torsney, C. and Fitzgerald, M., 2002). This predominantly A-fiber-induced spike activity appear to have a critical role in the formation of nociceptive circuits. Newborn rat pups have a high error rate in the direction of a tail flick on noxious stimulation than adults, which gradually improves over 3 weeks (Waldenstrom, A. *et al.*, 2003). The maturation is unaffected by daily noxious stimulation but blocking low-intensity tactile inputs from the tail with local anesthetic, during the critical 10-day period, prevents this postnatal tuning. Low-intensity tactile input from, for example, spontaneous twitching during sleep could play a role in shaping nociceptive circuits in early life (Petersson, P. *et al.*, 2003).

Postnatal maturation and tuning of nociceptive circuits critically depends upon the postnatal development of excitatory and inhibitory neurotransmitter/receptor function in the neonatal dorsal horn. The developmental pharmacology of spinal pain pathways has been an area of intense recent interest (Pattinson, D. and Fitzgerald, M., 2004; Fitzgerald, M., 2005) and some important features are shown in Box 2. The properties of immature

Box 2 The development of excitatory and inhibitory transmission in developing spinal pain circuits

Glutamate AMPA and NMDA receptors are highly expressed in the newborn dorsal horn and their expression decreases and becomes spatially organized with age. This is accompanied by changes in subunit composition leading to greater AMPA-dependent Ca^{2+} influx, altered receptor kinetics, greater NMDA receptor affinity, and increased Mg^{2+} sensitivity in neonatal spinal neurons (Watanabe, M. *et al.*, 1994; Jakowec, M. W. *et al.*, 1995; Albuquerque, C. *et al.*, 1999; Bardoni, R., 2001; Green, G. M. and Gibb, A. J., 2001; Stegenga, S. L. and Kalb, R. G., 2001). Presynaptic Ca^{2+}-permeable KA receptors found on IB4+ve C cells switch to a Ca^{2+}-impermeable form early in the first postnatal week (Lee, C. J. *et al.*, 2001).

Despite early expression of GABA and glycine and their receptors, newborn lamina II neurons exhibit only GABA mIPSCs (Baccei, M. L. and Fitzgerald, M., 2004) probably due to low levels of gephyrin, the postsynaptic scaffolding protein (Bremner *et al.*, 2005). There is also a fourfold acceleration in the decay rate of GABA mIPSCs in laminae I–II neurons between P8 and P23 triggered by local neurosteroid release (Keller, A. F. *et al.*, 2004). $GABA_AR$ activation in the developing dorsal horn can be excitatory rather than inhibitory, due to the high intracellular Cl^- concentration in immature neurons producing a positive E_{Cl}. $GABA_AR$ activation depolarizes some lamina II cells but the response becomes exclusively hyperpolarizing by P6–P7 (Baccei, M. L. and Fitzgerald, M., 2004). This is probably due to the onset of expression of the K^+–Cl^- cotransporter KCC2 which decreases $[Cl]_i$ over the postnatal period. However, E_{Cl} is always more negative than action potential threshold at P0–P1 suggesting that GABA will still inhibit the firing of newborn superficial dorsal horn neurons (albeit less effectively than in the adult).

Both presynaptic and postsynaptic $GABA_BRs$ are functional from birth in the neonatal dorsal horn, but seem to be regulated differently over the early postnatal period (Baccei, M. L. and Fitzgerald, M., 2004).

synaptic transmission tends to enhance calcium influx into developing dorsal horn neurons compared to adult neurons, which may be important for a variety of developmental processes including synapse formation and remodeling.

5.11.3 The Development of Ascending Pain Pathways

Following integration in the dorsal horn, sensory and nociceptive information is conducted to supraspinal centers via ascending tracts to targets in the brainstem, midbrain, hypothalamus, thalamus, and amygdala. A key ascending pathway involved in pain and hyperalgesia arises from lamina I of the dorsal horn of the spinal cord, particularly neurokinin 1 (NK1) expressing neurons receiving Aδ- and C-fiber nociceptive input, which project to the parabrachial area of the brainstem. These neurons then project to the amygdala (affective components of pain) and the hypothalamus (autonomic functions such as changes in heart rate and blood pressure). Outputs from these structures are passed via the periaqueductal gray (PAG), which in turn sends descending projections back to the dorsal horn in a spinobulbar spinal loop. Descending projections to the dorsal horn arise from the brainstem nuclei, nucleus raphe magnus (NRM), raphe dorsalis, reticularis, paragigantocellularis (NRPG), as well as locus coeruleus, PAG, and mesencephalic reticular formation (Todd, A. J. *et al.*, 2000; Mantyh, P. W. and Hunt, S. P., 2004; Suzuki, R. *et al.*, 2004; Ding, Y. Q. *et al.*, 1995; Marshall, G. E. *et al.*, 1996).

Little is known about the development of ascending spinothalamic and spinoparabrachial tracts. In the rat, neurogenesis of dorsal horn projection neurons is complete by E16 having followed a systematic pattern of migration and settlement in the dorsal horn related to their axon trajectories (Nissen, U. V. *et al.*, 2005). The projecting axons grow up the spinal cord prenatally (Bice, T. N. and Beal, J. A., 1997); spinothalamic tract fibers reach the thalamus just before birth at E19. In the rat, afferents appear to reach the thalamus by E19 (Higashi, S. *et al.*, 2002) while in the sheep, projection fibers from dorsal horn cells are in the thalamus approximately two-thirds through gestation (Rees, S. *et al.*, 1994; Ding, Y. Q. *et al.*, 1995). The thalamocortical axon (TCA) projection originates in dorsal thalamus, conveys sensory input to the neocortex, and has a critical role in cortical development. Information about the development of these pathways is entirely from visual and somatosensory (whisker) pathways in rodents and their relevance to nociceptive processing can only be inferred. Recently, however, a study by Man S. H. *et al.* (2005) has shown the presence at birth of the NK1+ve lamina 1 ascending projection from the DH to the parabrachial area of the brainstem using retrograde tracing and c-fos immunostaining. The outgrowth of axons from the thalamus to the cortex begins at E13–E14 in rodents just before the arrival of the first cells migrating into the preplate zone. The migration of cortical neurons from the proliferative neuroepithelium lining the telencephalic ventricle to the cortical plate is highly complex and tightly regulated (Meyer, G., 2001). Thalamic axons and preplate fibers meet in the lateral part of the internal capsule at E15 and grow in association with early corticofugal axons, right up to the cortical subplate. The topography of thalamic axons is maintained throughout the pathway and they reach the cortex by associating with the projections of a number of preexisting cells, including the preplate scaffold. These cells invade the cortical plate 24–48 h later and form functional synaptic connections in the cortical plate around E18–E19. At birth, thalamic axons have extended into cortical layers IV, V, and VI in a topographically precise manner and exhibit a periphery-related pattern in layer IV (Schlaggar, B. L. and O'Leary, D. D., 1994; Molnar, Z. *et al.*, 2003). The spatial distribution of thalamic synapses onto cortical neurons (predominantly found at dendritic spines) is established at least as early as P11 in the somatosensory cortex of the mouse (Lev, D. L. *et al.*, 2002).

5.11.4 Pain and the Developing Cortex

The development of specific cortical areas is dependent upon both extrinsic influences from thalamocortical input and intrinsic genetic controls such as the transcription factors Emx2 and Pax6 (O'Leary, D. D. and Nakagawa, Y., 2002). This process extends over several months in man compared to the mouse cortex that requires a week (Angevine, J. B. and Sidman, R. L., 1961). In man, the generation and migration of cortical neurons begins in the fifth gestational week (O'Rahilly, R. and Muller, F., 1994) and continues until week 22 (Sidman, R. L. and Rakic, P., 1973). Following the arrival of neurons at their correct destination, they begin to differentiate and to extend dendritic fields. It is in the last 2 months of gestation that the characteristic folding of the cortex

into sulci and gyri takes place (Fees-Higgins, A. and Larroche, J. C., 1987).

One area of interest is the anterior cingulate cortex (ACC) that appears to play an important role in the affective and cognitive aspects of pain, but little is known of the development of this region. Ultrasonic scans taken from preterm neonates have confirmed that at week 28 the ACC is fully developed (Huang, C. C., 1991).

Subplate neurons (SPn) play an important role in the formation of thalamocortical connections during early development and show glutamatergic and GABAergic spontaneous synaptic activity. Whole-cell recordings from SPn in somatosensory cortical slices of postnatal day 0–3 rats, showed that SPn receive distinct functional synaptic inputs arising from the thalamus, cortical plate, and other SPn mediated by AMPA and NMDA receptors (Hanganu, I. L. *et al.*, 2002; Luhmann, H. J. *et al.*, 2003). GABA activity is depolarizing at this age (see Box 2). Electrophysiological analysis of cortical cells at P7 shows them to be organized in columns as in the adult but to have larger receptive fields, similar to that discussed above for the spinal cord (Armstrong-James, M. A., 1970; Armstrong-James, M., 1975). Human somatosensory potentials evoked by electrical stimulation are observed at 29 weeks (Klimach, V. J. and Cooke, R. W., 1988) while preliminary studies using infrared spectroscopy during routine clinical heel lances suggest that a cortical blood flow response is present as early as 25 weeks (Slater, R. *et al.*, 2006).

While axonal growth and early topographic arrangement of thalamocortical fiber pathways do not rely on activity-dependent mechanisms requiring evoked neurotransmitter release (Molnar, Z. *et al.*, 2002), the formation of cortical circuits is highly dependent upon normal sensory experience. The postnatal plasticity of cortical circuits has been studied in great detail for the visual (Yao, H. and Dan, Y., 2005) and somatosensory whisker barrel cortex (Fox, K., 2002), but little is known about the effect of nociceptive activity upon cortical development (Anand, K. J., 2000).

5.11.5 Pain and the Developing Limbic System

The amygdala is a part of the limbic system and plays a key role in the emotional evaluation of sensory stimuli (Davis, M., 1998a; Aggleton, J. P., 1999; Gallagher, M. and Schoenbaum, G., 1999; Maren, S., 1999; Ledoux, J. E., 2000b; Cardinal, R. N. *et al.*, 2002; Davidson, R. J., 2002; Zald, D. H., 2003). In the rat, the amygdala is a complex of 13 nuclei and cortical regions and their subdivisions. There is some debate as to whether the amygdala should be considered a single entity or as a collection of functionally diverse nuclei that share some anatomical and physiological similarities (Aggleton, J. P. and Saunders, R. C., 2000). There are both direct and indirect nociceptive inputs to the laterocapsular part of the central nucleus of the amygdala (the nociceptive amygdala) and the whole central area supplies the major output forming widespread connections with forebrain areas, the hypothalamus and the brainstem (Pitkanen, A. *et al.*, 1998; Davis, M., 1998b; Aggleton, J. P. and Saunders, R. C., 2000; Ledoux, J. E., 2000a; Bourgeais, S. *et al.*, 2001; Neugebauer, V. and Li, W., 2002; 2003; Li, W. and Neugebauer, V., 2004).

Neurons in the amygdala of the rhesus monkey are generated during a 3-week period very early in gestation (E30–E50 of a 165-day gestation; Kordower, J. H. *et al.*, 1992). This neurogenesis appears to occur simultaneously within all the amygdalal nuclei. This pattern has also been reported in humans (Humphrey, T., 1968; Nikolic, I. and Kostovic, I., 1986). In the rodent, LOM-homeodomain genes have been shown to play a role in the segregation of embryonic amygdalal cells into appropriate groupings and this family of genes plays a fundamental role in the development of every single amygdalal nucleus (Remedios, R. *et al.*, 2004). The distribution of opiate receptors in the amygdala of a 1-week-old monkey appears the same as in the adult indicating early neurochemical maturation (Bachevalier, J. *et al.*, 1986). Widespread connections to and from the monkey amygdala at 1 week of age appear to be pruned over the postnatal period (Webster, M. J. *et al.*, 1991). The same connections are likely to occur over the first 2 postnatal weeks in rats.

5.11.6 The Development of Descending Pain Pathways

Brainstem descending pathways form a major mechanism in the control of pain transmission (Pitkanen, A. *et al.*, 1998; Ren, K. and Dubner, R., 2002; Gebhart, G. F., 2004) and there is more known about the development of these descending controls compared to the ascending systems.

Brainstem nuclei differentiate between E11 and E16 in the rat and all other major brain systems are morphologically identifiable by E18 (Altman, J. and Bayer, S. A., 1984; Momose-Sato, Y. *et al.*, 2001). In the rat embryo, the parabrachial area can be visualized histochemically from at least E17 (Cholley, B. *et al.*, 1989) (Figure 1).

As with ascending tracts, axons from brainstem nuclei appear to grow down the spinal cord well before birth (Cabana, T. and Martin, G. F., 1984). Injections of horseradish peroxidase into lumbosacral spinal cord of the neonatal rat label brainstem nuclei with similar density to that seen in the adult (Leong, S. K., 1983; Fitzgerald, M. *et al.*, 1987) but it is unclear at what stage these axons begin producing collaterals that innervate the dorsal horn and make synapses with their target cells. Mapping degenerating axons and synaptic endings following thoracic hemisections

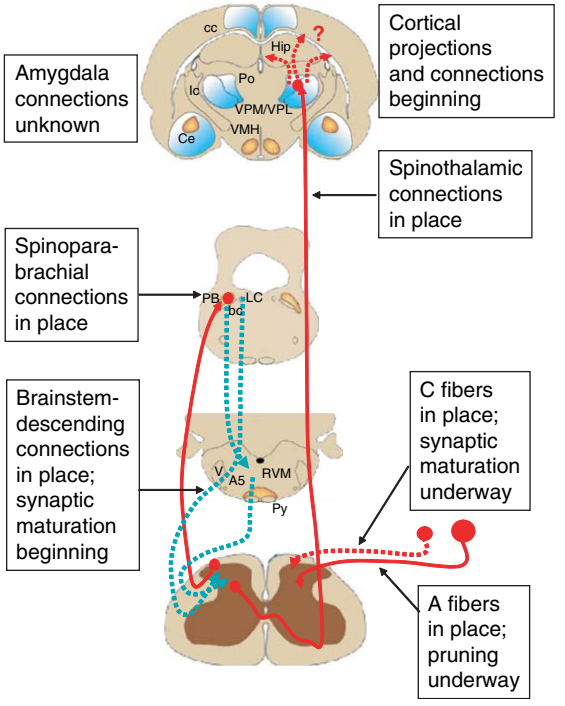

Figure 1 Diagram summarizing the state of development of ascending and descending pathways involved in the transmission of pain in the newborn rat. It is important to remember that changes in the anatomy of the pathways depicted here are also accompanied by changes in the physiology and neurochemistry of these pathways also. Additionally, the maturation of human nociceptive pathways occurs over different and as yet unknown time courses from those discussed here. Adapted from Hunt, S. and Mantyh, P. 2001. The molecular dynamics of pain control. Nat. Rev. Neurosci. 2, 83–91.

of the spinal cord at various postnatal stages suggests that descending axon collaterals innervate the intermediate and central gray from birth but that they are not found in the dorsal horn until P15 (Gilbert, M. and Stelzner, D. J., 1979).

Descending inhibitory pathways traveling from the brainstem via the dorsolateral funiculus of the spinal cord to the dorsal horn grow down the spinal cord early in fetal life, but they do not extend collateral branches into the dorsal horn for some time. Stimulation of the dorsolateral funiculi (DLF) fails to produce descending inhibition of C-fiber-evoked activity in neonatal rats before P9, but high-intensity stimulation produced descending inhibition at P18. By P22–P24 more typical adult responses were observed (Fitzgerald, M. and Koltzenburg, M., 1986). Similarly, the inhibition of C and Aδ activity in the dorsal horn by PAG stimulation via the DLF that is clearly observed in adults (Basbaum, A. I. and Fields, H. L., 1978) cannot be produced in rat pups before P21 (van Praag, H. and Frenk, H., 1991). Diffuse noxious inhibitory control (DNIC), measured as a reduction in noxious-evoked dorsal horn c-fos expression in the presence of an inflammatory stimulus elsewhere on the body, also develops between P12 and P21 (Boucher, T. *et al.*, 1998).

The delayed postnatal onset of functional descending inhibition, despite the presence of DLF terminals in the dorsal horn may be due to immaturity of neurotransmitter/receptor interactions (see below) or delayed maturation of critical interneurons. It has been suggested that the maturation of descending inhibition is dependent upon afferent C-fiber activity, because rats treated with capsaicin at birth have reduced inhibitory controls as adults (Cervero, F. and Plenderleith, M. B., 1985). The lack of descending inhibition in the neonatal dorsal horn means that there is no endogenous analgesic system to dampen noxious inputs as they enter the CNS and their effects may therefore be more profound than in the adult. It also explains why stimulus-produced analgesia from the PAG is not effective until P21 in rats (van Praag, H. and Frenk, H., 1991).

5.11.7 Development of Neurotransmitter/Receptor Function in Descending Pathways

It is widely accepted that 5-HT is the most relevant neurotransmitter with respect to the descending control of spinal cord excitability. Descending

serotonergic pathways predominantly mediate descending inhibitory control over spinal cord excitability, but 5-HT is involved in both antinociceptive and pronociceptive effects depending upon the subtype of receptor that it is acting upon (Millan, M. J., 2002; Gebhart, G. F., 2004). An excitatory, pronociceptive role has been attributed to the 5-HT_3 receptor (Suzuki, R. *et al.*, 2002). In the adult, descending inhibition and excitation are conveyed rostrocaudally via different spinal pathways, the DLF and ventral/ventrolateral funiculi (VLF), respectively (Millan, M. J., 2002), and since both of these tracts appear in the embryonic period, both types of control may also be possible in the newborn. Neurons that produce 5-HT (serotonin) are amongst the earliest to be detected in the developing CNS (Rubenstein, J. L., 1998) with the mesencephalon containing detectable levels by E12 (E12; Aitken, A. R. and Tork, I., 1988). 5-HT containing descending neurons is present in the rat between E15 and E19 (Lidov, H. G. and Molliver, M. E., 1982; Lakke, E. A., 1997), those arising from the raphe nuclei are present in the cervical cord by E14 and in the lumbar cord by E16–E17. 5-HT fibers were not found to innervate the dorsal horn until E19 (Rajaofetra, N. *et al.*, 1989). Examination of the pre- and postnatal development of the descending serotonergic pathways to the spinal cord show that the maturation of 5-HT terminals occurs in a ventral to dorsal direction such that innervation of the lumbar dorsal horn does not occur until P14 and the adult pattern of high-density terminals in lamina II at P21 (Bregman, B. S., 1987). Direct application of 5-HT to the neonatal spinal cord *in vitro* is effective in very young superficial dorsal horn cells, suggesting that at least some 5-HT receptors are functional from birth (Li, P. and Zhuo, M., 1998).

Although 5-HT is the most important neurotransmitter, other monoaminergic and peptidergic compounds must also be considered with regard to the descending control of spinal cord excitability. The major noradrenergic input to the dorsal horn is from the locus coeruleus (LC) and adjacent noradrenergic nuclei in the brainstem. Activation of this pathway leads to the release of noradrenaline that acts postsynaptically on α_2-adrenergic receptors to produce a decrease in excitability and a concomitant analgesia (Sagen, J. and Proudfit, H. K., 1984; Jones, B. E. 1991; Jasmin, L. *et al.*, 2002). Noradrenaline containing terminals appear earlier in the dorsal horn than serotonin (Loizou, L. A., 1972; Commissiong, J. W., 1983) and levels are generally mature by 2 weeks postnatally. As with 5-HT, the development of the noradrenergic system in the ventral horn precedes that in the dorsal horn. Expression of the α2A receptor mRNA is observed in high levels in the dorsal horn from E19 and is downregulated postnatally (Winzer-Serhan, U. H. *et al.*, 1997), which has led to the proposal that noradrenaline has a trophic role in the developing cord (Huang, Y. *et al.*, 2002). Recent functional studies have shown that the local spinal cord application dexmedetomidine, the potent α2A agonist, has antinociceptive and antihyperalgesic actions from at least P3 (Walker, S. 2005).

Dopamine is also released by descending tracts; the main source is from the A11 (posterior) region of the hypothalamus (Commissiong, J. W. *et al.*, 1978; Commissiong, J. W. and Neff, N. H., 1979; Swanson, L. W. and Kuypers, H. G., 1980), which provide extensive networks of dopamine-containing fibers in the dorsal horn and lamina X of the spinal cord (Skagerberg, G. *et al.*, 1982; 1988). In the rat, dopamine containing neurons appear in the mesencephalon at E12–E13 (Olson, L. and Seiger, A., 1972) and levels of dopmaine appear to increase throughout development with particularly high levels being found in the solitary tract in the brainstem (Moore, R. Y. and Bloom, F. E., 1978).

Numerous other nonmonoaminergic transmitters are found in the terminals of descending pathways in the spinal cord including histamine, vasopressin, and oxytocin. Other transmitters released by descending projections are also present in intrinsic DH neurons. Of these, acetylcholine is the most prominent, having both a pro- and antinociceptive effect depending on the subtype of the receptor activated. Other neurotransmitters in the category are GABA and glycine. Cholinergic neurons in the brainstem generally develop later than catecholaminergic systems with levels of cholinergic markers such as choline acetyltransferase being only a few percent of the levels seen in the adult rat at birth but start to increase rapidly after P10 (Diebler, M. F. *et al.*, 1979).

A major peptidergic descending input from the brainstem to the dorsal horn of the spinal cord is via enkephalin and other opioid peptides (pre-proenkephalin, pre-prodynorphin, pre-proendomorphin, pre-pro-opiomelanocortin (POMC), and orphaninFQ). Opioids play an important role in pain transmission both by initiating the descending controls from the brainstem and by directly reducing the evoked activity of C and Aδ fibers in the dorsal horn via presynaptic opiate receptors. There is considerable postnatal development of this receptor

expression, with neonatal rats not only having a higher density but also a less selective distribution of μ-opioid receptors on DRG cells (Nandi, R. *et al.*, 2004). Morphine has a markedly higher analgesic efficacy in young rats in mechanical but not thermal noxious tests but it is not known whether this results from central or peripheral regulation of opioid pathways (Nandi, R. and Fitzgerald, M., 2005).

5.11.8 The Development of Persistent Pain

While it is essential to understand the underlying development of nociception, tissue injury, inflammation, and nerve damage can lead to more persistent pain that lasts for days, weeks, or months. Such pains arise from central sensitization and changes in gene expression as triggered by intense and sensitized peripheral nociceptor inputs (Woolf, C. J. and Salter, M. W., 2000).

Cutaneous mechanical thresholds fall in neonatal rat pups following local carrageenan injection (Marsh, D. *et al.*, 1999) and mustard oil application (Jiang, M. C. and Gebhart, G. F., 1998) but the effect is less at P3 than at P21. This may partly reflect peripheral nociceptor terminal immaturity. C fibers are capable of peripheral sensitization from before birth (Koltzenburg M., and Lewin, G. R., 1997) but peripheral C-fiber terminals do not release sufficient SP to produce neurogenic extravasation until P10 (Fitzgerald, M., and Gibson, S., 1984). Electrophysiological studies *in vivo* show that sensitization of dorsal horn cells can be observed 2–5 h after carageenan inflammation of the hindpaw at all ages although the exact pattern of effects is age dependent (Fitzgerald, M. and Jennings, E., 1999; Torsney, C. and Fitzgerald, M., 2003). In slice preparations, NMDA-dependent C-fiber-evoked depolarization of spinal cord cells and windup of cells to repeated C-fiber stimulation has been demonstrated in the young (8–14 days) spinal cord (Sivilotti, L. G, *et al.*, 1993). Recently, the role of descending brainstem excitatory pathways in maintaining persistent pain have been emphasized (Gebhart, G. F., 2004), but the developmental regulation of this system has not been investigated.

In adults, partial nerve injury can trigger neuropathic pain, charcterized by a lowered mechanical sensitivity or allodynia. In postnatal animal models of neuropathic pain, this allodynia is not observed until the animals are over 3 weeks old (Howard, R. F. *et al.*, 2001). This is interesting in view of the substantial cell death that occurs in the DRG of axons damaged in early life compared to adults (Yip, H. K. *et al.*, 1984; Benn, S. C. *et al.*, 2002) followed by transganglionic degeneration and subsequent withdrawal of central terminals (Bondok, A. A. and Sansone, F. M., 1984; Aldskogius, H. and Risling, M., 1989), sprouting of adjacent, intact axon collaterals into the denervated region (Fitzgerald, M., 1985; Fitzgerald, M. *et al.*, 1990; Shortland, P. and Fitzgerald, M., 1994) and disruption of the somatotopic organization of central terminals within the dorsal horn and cortex (Kaas, J. H. *et al.*, 1983). Clearly these changes do not trigger pain. One possibility is that the central microglial and immune responses that follow nerve injury in the adult and may contribute to neuropathic pain (Marchand, F. *et al.*, 2005) are not activated in the immature spinal cord.

There is also evidence that injury at a critical period of development may lead to long-term alterations in sensory processing resulting in hypo- or hyperalgesia (Lidow, M. S., 2002). The mechanisms underlying this are poorly understood. It is possible that early tissue damage, which is known to release excess neurotrophins into the wounded area (Constantinou, J. *et al.*, 1994) not only sensitizes peripheral nociceptors, but also permanently influences nociceptor development as described above. Alternatively central changes in activity-dependent connectivity are produced because of the increased barrage of C-fiber nociceptor input at a time when synapses are still forming (Fitzgerald, M. and Walker, S. M., 2003). Central changes in transmitter–receptor expression may also occur. Early inflammatory pain leads to an increase in expression in the PAG of serotonin receptors (5HT1A, 5HT1D, 5HT2A, 5HT2C, 5HT4), NR2D and NR3A subunits of the NMDA receptor, $GABA_A\gamma 2$ and $GABA_A\theta$ subunits, the NK1, and the CCK-2 receptor. As well as being hypoalgesic, these animals exhibited decreased anxiety and greater stress-coping ability; this was indexed by better performance on the elevated plus maze and decreased basal and stress-induced neuroendocrine markers of anxiety and stress (Anseloni, V. C. *et al.*, 2005). For further review of this area, see Baccei M. L. and Fitzgerald M. (2005).

5.11.9 Concluding Remarks

In this chapter we have attempted to briefly review what is currently known about the development and maturation of pain pathways. While our knowledge of

Box 3 Development of pain pathways in humans

Because human infants cannot report pain, we have to use indirect physiological and behavioral methods to assess its existence and severity and there is considerable debate on how best to measure pain in infants (Stevens, B. J. and Franck, L. S., 2001).

From 23 weeks of gestational age, human fetuses mount a hormonal response when needles are inserted into the innervated intrahepatic vein (Giannakoulopoulos, X. *et al.*, 1994). Noxious activation of nerve endings stimulates central pathways (most likely through the fetal hypothalamic–pituitary–adrenal axis), producing a biochemical stress response, although the link between perceived pain and the hormonal stress response is unpredictable, even in adults. Hormonal responses are also used to measure pain in the youngest preterm infants (~24–26 weeks), along with many other physiological measures such as heart rate variability, crying and palmar sweating and motor activity (Stevens, B. J. and Franck, L. S., 2001), and characteristic facial expressions (Craig, K. D. *et al.*, 2002). Many of these measures can be applied to pain related to a particular noxious event, such as a needle prick, but are harder to use for persistent pain. Studies using cutaneous reflexes evoked by stimulation in and around an area of injury, show that infants display cutaneous sensitization or hyperalgesia lasting days and weeks (Andrews, K. and Fitzgerald, M., 2002; Andrews, K. *et al.*, 2002), consistent with laboratory studies. Nothing is known of the maturation of descending brainstem controls in human infants.

True pain experience requires functional maturation of higher brain centers and recent studies using infrared spectroscopy during routine clinical heel lances suggest that a cortical blood flow response is present as early as 25 weeks (Slater, R. *et al.*, 2006).

the development of spinal nociceptive pathways has increased considerably in recent years (Fitzgerald, M., 2005), the understanding of the structural and functional maturation of supraspinal centers involved in the affective and nociceptive components of pain is severely lacking. With rapid improvements in medical knowledge and technologies, it is now possible to treat children born at increasing premature stages of development. This requires long periods of hospitalization and large numbers of often invasive procedures that in an adult or older child would be considered painful (Box 3), leading to the administration of analgesic and sedative compounds. We know that neonates respond to pain but the pathways differ in important ways from those in adults. Until we understand more of the functional development and maturation of the central neuronal elements involved in the experience of pain, the best course of analgesic action in infancy remains unclear.

5.12.1 General Background

The topographical organization of the somatosensory input to the spinal cord has traditionally been regarded as a somatotopically organized map of the body (Molander, C. and Grant, G., 1985; Mirnics, K. and Koerber, H. R., 1995; Silos-Santiago, I. *et al.*, 1995; Wilson, P. and Kitchener, P. D., 1996; Brown, P. B. *et al.*, 1997; 2004; 2005), with different body parts represented in different central nervous system (CNS) areas and the size of the representation being a function of receptor density and, to some extent, practise (see Blake, D. T., *et al.*, 2002). Most studies on the body representation have been focused on the sensory discriminative aspects (Brown, P. B. *et al.*, 2004; 2005). However, a major function of the spinal cord is to use the sensory information to control skeletal muscles. It has therefore been suggested that the somatosensory input may be primarily organized in a motor frame of reference (Levinsson, A. *et al.*, 2002). Such a view might explain some of the oddities with the known topography. For example, in the dorsal horn, there is an extensive overlap of afferent terminals from different body parts, and the sequence of the representation from distal to proximal body parts is neither continuous nor sequential (Levinsson, A. *et al.*, 2002). Moreover, the phenomenon of somatotopically inappropriate terminations, that is, primary afferents terminating outside the main projection area, might be explained if different motor systems requiring sensory information from same body region have different locations in the spinal cord.

To be useful in motor control, somatosensory information must be encoded with respect to body anatomy and movement patterns produced by the sensorimotor circuits. This is a computationally demanding task since the multisensory information (nociception, pressure, temperature, joint angles, muscle force, and length) arises from a complex body constitution. Understanding how sensory information is processed by spinal sensorimotor circuits and how the adult organization emerges during development is therefore a major task. This review will deal with the current literature on the modular organization of the spinal cord and the role of somatosensory imprinting in establishing an action-based sensory encoding in these modules.

5.12.2 Modular Organization of Sensorimotor Circuits in the Spinal Cord

During the last 10 years, the concept of a modular organization of the spinal cord has grown stronger. The idea of a modular organization of motor circuits in CNS is not new and, for the spinal cord, was proposed already in 1981 by Grillner, S. for locomotor circuits (unit bursters causing rhythmic activity around a joint) and later for circuits controlling scratch reflexes in the turtle (Mortin, L. I. *et al.*, 1985; Stein, P. S. *et al.*, 1998; Berkowitz, A., 2001). However, although a modular organization is conceivable, it is not yet clear exactly what constitutes a module in these rhythm-generating systems, the extent to which the different modules overlap in space, and how sensory information is related to the function of these modules (Tresch, M. C. *et al.*, 2002).

A modular type of reflex organization in the mammalian spinal cord was first demonstrated for the nociceptive withdrawal reflex (NWR) system in the rat (Schouenborg, J. and Kalliomäki, J., 1990; Schouenborg, J. *et al.*, 1992), but subsequently also in cats (Levinsson, A. *et al.*, 1999), mice (Thelin, J. M. and Schouenborg, J., 2003), and humans

(Sonnenborg, F. A. *et al.*, 2000). Here, the word modular is used synonymous to the term functional unit of a system, that is, not alluding to the existence of different motor systems, such as stepping, standing, scratching, or withdrawal reflex systems. For the NWR system, each excitatory module preferentially acts on a single muscle and performs a detailed sensorimotor transformation resulting in a graded withdrawal of the limb (or part of the limb) from its receptive field. For each excitatory NWR module, the input strength has a characteristic pattern on the skin that mimics the pattern of withdrawal efficacy in a standing position when the principal output muscle of the module contracts (Figure 1; Schouenborg, J. and Weng, H.-R., 1994). In a sense, the pattern of withdrawal (or unloading) efficacy is imprinted on the receptive field of the module. Neurones that encode sensory input in this motor frame of reference, termed reflex encoders (Schouenborg, J. *et al.*, 1995), are mainly located in deep dorsal horn laminae IV–VI. These neurones receive and weight the multisensory input from both tactile Aβ and nociceptive Aδ and C afferent fibers in proportion to the withdrawal/unloading action of the modules in a standing position (Figure 2). It is worth noting that, although the nociceptive input is stronger than that from tactile input, the strength of the input mediated by different types of afferent fibers is weighted in the same way. In fact, a large proportion of the wide dynamic range neurones, that is, neurones receiving a convergent input from tactile and nociceptive receptors, often referred to as wide dynamic range neurons, in the deep layers of the fifth lumbar segment, appear to be of the reflex encoder type. Within the L4–5 segments, reflex encoders for the interossei, flexor digitorum longus, gastrocnemius, peronei, and extensor digitorum longus muscles are located in a mediolateral sequence reminiscent of the corresponding topographical organization of the motoneuron columns in the ventral horn. Hence, the reflex encoders appear to be located in discrete pools that have a musculotopic organization.

A corresponding set of inhibitory reflex modules also exists. In this case, the receptive fields correspond to the graded movement of the skin area toward external stimulation (i.e., increase in load) on contraction of the muscle in the module (Weng, H.-R. and Schouenborg, J., 1996). As a result of this organization, the excitatory and inhibitory modules are engaged to a degree that is proportional to their respective withdrawal/loading efficacy on skin stimulation.

The same principles of sensorimotor transformation as found for rat withdrawal reflexes also apply to the cat, mice, and humans (Levinsson, A. *et al.*, 1999 in cats; Sonnenborg, F. A. *et al.*, 2000; Thelin, J. M. and Schouenborg, J., 2003). Interestingly, muscles with different function in two different species exhibit corresponding differences in the receptive fields of the withdrawal reflexes. Thus, withdrawal reflexes elicited in dorsiflexors are much weaker in the cat than in the rat and vice versa for reflexes to plantar flexors. Cats stand on their digits, whereas rats stand on the whole plantar surface. In the standing position, the dorsiflexors of cat digits are much less effective in withdrawing the plantar skin than the corresponding muscles in rats and vice versa for plantar flexors. These findings are consistent with the view that these reflexes consist of adaptive modules (see Section 5.12.4).

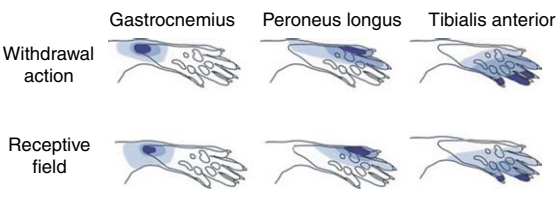

Figure 1 Action-based sensory encoding. Typical distributions of sensitivity and corresponding withdrawal action for three muscles are shown. Low, medium, and high dot density indicates areas of the skin from which the evoked responses were 0–30%, 30–70%, and 70–100% of maximal response, respectively. Adapted from Schouenborg, J. and Weng, H.-R. 1994. Sensorimotor transformation in a spinal motor system. Exp. Brain. Res. 100, 170–174.

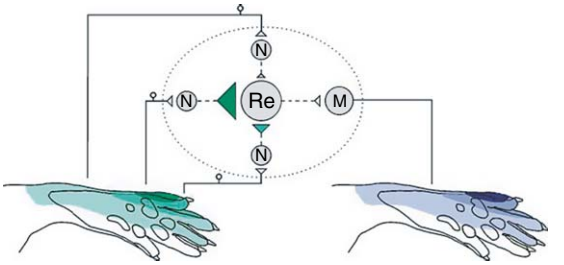

Figure 2 Schematic circuitry organization of a withdrawal reflex module. Nociceptive afferents from the receptive field (right) synapse with nociceptive neurones (N) in the superficial laminae of the dorsal horn. Reflex encoder neurones (Re) receive a weighted nociceptive input from superficially located neurones. Re project either directly or indirectly to motoneurones essentially controlling the action of a single muscle. Withdrawal efficacy of the module is shown to the right. Sensitivity in strength of primary afferent input and sensitivity in receptive fields is coded by color intensity. Tactile input is omitted for clarity.

Based on microstimulation in the dorsal horn of the spinal cord, a somewhat different modular organization of sensorimotor circuits acting on synergistic muscle groups was later proposed in frogs and rats (Tresch, M. C. and Bizzi, E., 1999; Bizzi, E. *et al.*, 2000, Saltiel, P. *et al.*, 2001). According to these authors, electrical and glutamatergic stimulation of the deep dorsal horn often results in a movement toward an equilibrium point, independent of the starting position of the limb. Here, the output of a module would include activity in two or more different muscles. Whether these findings reflect the existence of a fundamentally different type of reflex system than that of the withdrawal reflex system or the outcome of a combined stimulation of many withdrawal reflex modules is not clear at present. In a recent study, Avella and colleagues suggested, by analyzing electromyography (EMG) in frog hindlimbs during kicking, that a combination of a limited number of synergistic units was used for this behaviour (Avella, A. *et al.*, 2003).

5.12.3 Action-Based Sensory Encoding

By mapping tactile input to the dorsal horn, longitudinal cigar-shaped zones that weight the monosynaptic cutaneous input as a function of the unloading pattern caused by individual modules were found (Figure 3; Levinsson, A. *et al.*, 2002). This was a surprising finding in that it indicates that sensory input to the spinal cord gets organized and weighted in a motor frame of reference already at the level of the first-order synapses and that there may, consequently, not be a true 'map' of the body in the spinal cord as previously thought (Molander, C. and Grant, G., 1985; Mirnics, K. and Koerber, H. R., 1995; Silos-Santiago, I. *et al.*, 1995; Brown, P. B. *et al.*, 1997). Given that a main function of the spinal cord is to translate sensory information into movement corrections, an action-based sensory encoding do, however, appear to be an economical and fast way of processing the sensory information.

There are many reasons to think that action-based sensory encoding is fundamental also for higher-order motor systems. For example, the C1, C3, and X zones in the anterior cerebellar lobe is divided into microzones, where each microzone is defined by its climbing fibre input from a specific receptive field on the skin (Garwicz, M., 2002; Garwicz, M. *et al.*, 2002; Apps, R. and Garwicz, M., 2005). These climbing fibers encode the sensory input in the same way as individual spinal modules, that is, as a function of the unloading pattern caused by single muscle contraction.

5.12.4 Functional Adaptation of Sensorimotor Circuits During Development

Given that the adult sensorimotor transformations performed by the spinal withdrawal reflex circuits reflect precisely weighted connections in modules, how can this weighting be achieved during development? While the gross topographical organization of interneurons of the spinal cord is likely to be guided by gradients of trophic substances during the development (Albright, T. D. *et al.*, 2000, Chen, A. I. *et al.*, 2006; Chen, C. L. *et al.*, 2006; Kramer, I. *et al.*, 2006), it is difficult to see how such mechanisms could encode the detailed strength of every connection in the networks. Recent studies on the NWR system provide some clues to this problem. The sensorimotor transformations performed by its modules are functionally adapted during the first postnatal weeks in the rat (Holmberg, H. and Schouenborg, J., 1996a). During this time, the strength of the erroneous (or inappropriate) connections becomes weaker, whereas the strength of the adequate connections becomes proportional to the unloading effect on the skin of muscle contraction. Moreover, during this time, NWR can adapt to both altered innervation of the skin caused by nerve sections (Holmberg, H. and Schouenborg, J., 1996b) and to altered movement patterns caused by tendon transfer in the neonatal rat (Holmberg, H. *et al.*, 1997). Blocking the sensory input during the time of functional adaptation abolishes the learning (Waldenström, A. *et al.*, 2003), indicating a role for sensory input. Notably, a selective block of the nociceptive input by EMLA salve did not have an effect as compared with vehicle treatment. The functional adaptation is not blocked unless tactile input is also blocked, indicating a key role for tactile input in tuning nociceptive connections (Figure 4(a)). This conclusion is strongly supported by the finding that tactile feedback ensuing on spontaneous motility in spinal sensorimotor circuits alters the nociceptive connection strengths in NWR modules during postnatal development (Figures 4(b)–4(c)); Petersson, P. *et al.*, 2003). Thus, the pattern of tactile inputs arriving in conjunction with the spontaneous movements has an instructive

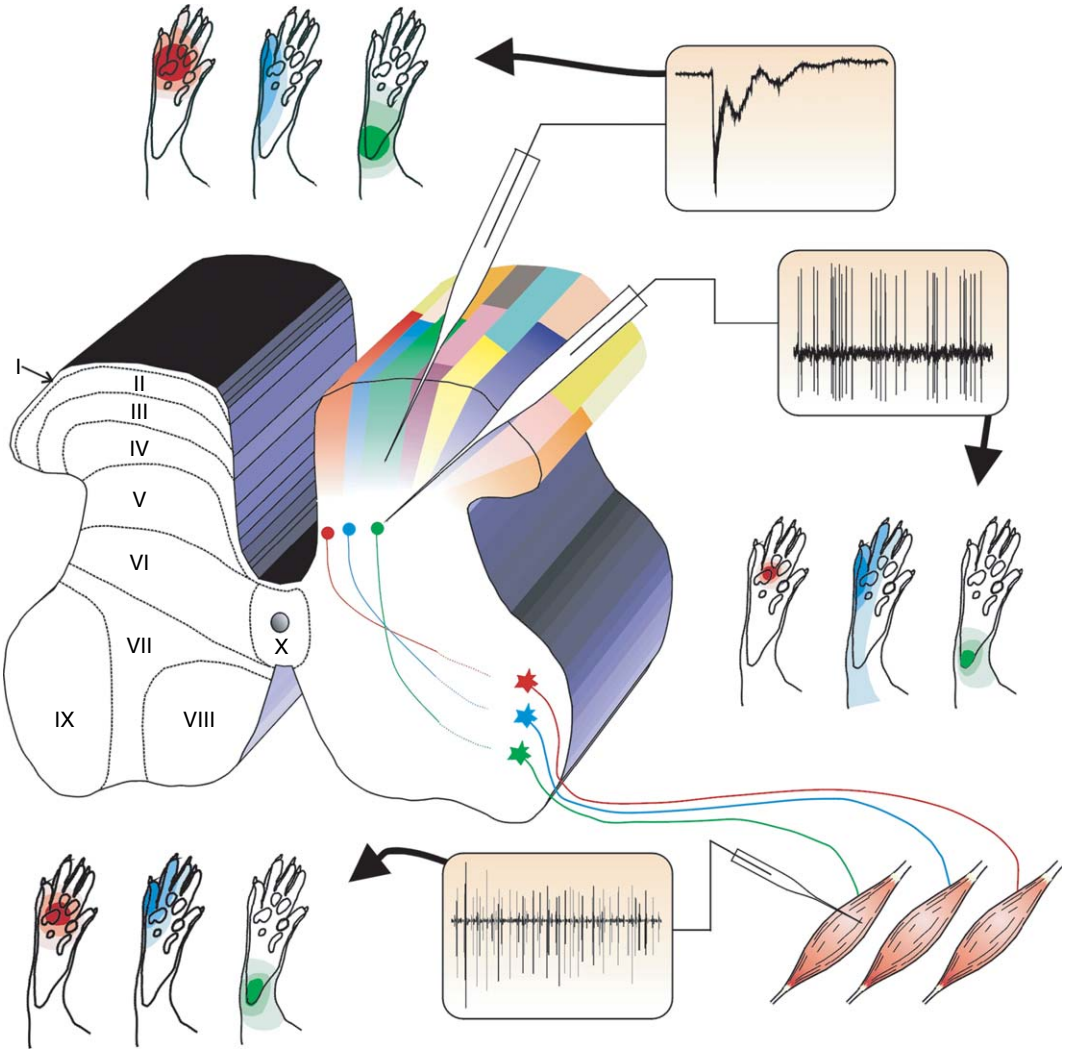

Figure 3 Schematic figure of proposed modular organization of the spinal cord. Columns of the dorsal horn receive a cutaneous input that has a specific weight distribution. This weight distribution is the same as that of nociceptive input to reflex encoders (interneurones that can encode the withdrawal reflex strength of individual modules) in deep dorsal horn. The reflex encoders are assumed to project to single muscles and weight the input according to the withdrawal efficacy of the output muscle. Sensitivity in strength of primary afferent input and sensitivity in receptive fields is coded by color intensity. Upper recordings, receptive fields of monosynaptic tactile field potentials; middle recordings, receptive fields of reflex encoders, bottom recordings, receptive fields of single muscles. Schematic indication of Rexed's laminae to the left.

role in the functional adaptation of the reflex modules. Uncorrelated input (given at random time points) does not cause a learning effect. Since this learning process results in an imprint of the withdrawal efficacy on the reflex modules, it was termed somatosensory imprinting (Holmberg, H. *et al.*, 1997; Petersson, P. *et al.*, 2003).

The finding that the strength of the nociceptive connections to the NWR network can be functionally adapted by tactile input discloses a hitherto unknown form of cross-modality learning in the spinal cord that solves the puzzle of how a pain-related system can be learned during postnatal development, despite the rare occurrence of noxious events. Notably, this novel form of unsupervised learning occurs during active sleep, characterized by atonia in the musculature. This state may be particularly advantageous for learning since the sensory feedback on muscle contraction stands out from a more or less silent background.

A hitherto neglected problem is how the myriad of different types of somatosensory primary afferents, conveying information from different sensory

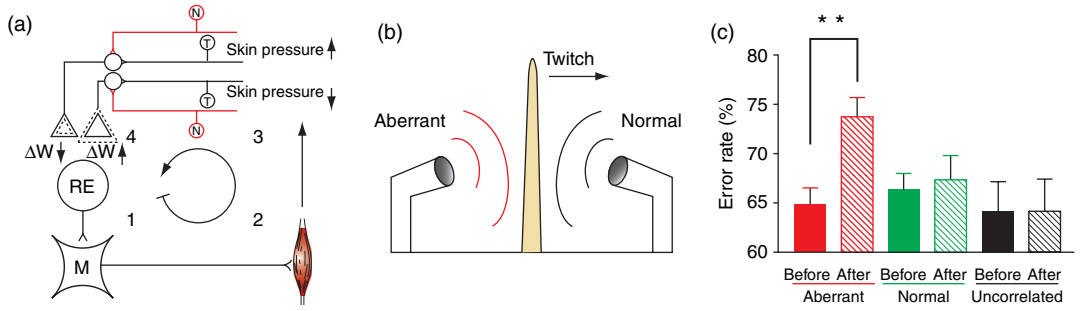

Figure 4 Somatosensory imprinting. (a) Proposed learning cycle underlying somatosensory imprinting. A learning cycle consists of the following chain of events. (1) Spontaneous bursts in reflex encoders (REs). (2) Motoneuron (M) activation leading to a muscle twitch that causes skin movement. (3) Increased or decreased skin pressure resulting in altered sensory input to pre-reflex encoder interneurons. Black lines (T) represent afferents from skin areas from where an increase and decrease, respectively, in low-threshold mechanoreceptor input would occur. Red lines (N) symbolize nociceptive afferents. (4) The strengths of erroneous connections (receiving increased tactile input) between pre-RE interneurons and REs are weakened and that of appropriate ones (receiving reduced tactile input) is strengthened (Dw = change in connection strength) (modified from Waldenström, A. *et al*., 2003). (b) Behavioural experiments. Schematic training set-up depicting aberrant and normal training protocol. Distal tail of a sleeping rat pup is shown. Air puffs directed to the skin surface moving toward or away from the air stream is termed aberrant or normal conditioning, respectively. One session of conditioning stimulation lasted for 2 h. Arrow indicates direction of spontaneous tail flick (modified from Petersson, P. *et al*., 2003). (c) The nociceptive withdrawal reflex (NWR) error rate (%) before and after aberrant or normal tactile stimulation (mean SE). The NWR error rate was significantly increased (Kruskal–Wallis and Dunnett's test $P < 0.01$) in rats given aberrant tactile feedback for 2 h (47 training sessions). Normal air-puff stimulation (53 training sessions) had no effect. Control experiments, using random air-puff stimulation (23 training sessions) or no stimulation (23 training sessions) did not affect NWR adaptation (Wilcoxon signed rank test $P = 0.65$ and $P = 0.37$, respectively), ruling out direct effects of the set-up, test stimulations, or of uncorrelated stimulation. (Adapted from Petersson, P., Waldenström, A., Fåhreaus, C., and Schouenborg, J. 2003. Spontaneous muscle twitches during sleep guide spinal self-organization. Nature 424(6244), 72–75.

modalities and locations, gets organized in the dorsal horn so that spinal multisensory modules receive topographically ordered information. Considering the apparent lack of somatotopic organization in the dorsal root ganglia and that different nerve fibre types enter the spinal cord by different routes and at different times during development, this is not a trivial problem. Indeed, recent data indicate that the adult body representation in the dorsal horn arises from an initially floating and plastic organization with many inappropriate connections through profound activity-dependent rewiring, involving both sprouting and elimination of afferent connections. In this process, tactile input seems to guide the alignment of tactile and nociceptive termination since disturbed tactile input patterns results in disturbed termination patterns of both tactile and nociceptive afferent fibers (Granmo, G. *et al*., 2002; Petersson, P. *et al*., 2004; Granmo, G. *et al*., 2005; 2007). The activity-dependent changes in the organization of the primary afferent termination in the spinal cord including changes in laminar termination patterns of tactile afferents are paralleled in time by reflex sensorimotor transformations, suggesting that the emerging action-based body representation is at least partly imprinted on the first-order synapses. Importantly, these findings suggest that the adult action-based sensory encoding emerges by sensorimotor circuits probing the patterns of tactile input that ensue on movements caused by the effector muscles.

Spontaneous movements are a ubiquitous phenomenon during embryonic development in all vertebrates and mammals (De Vries, J. I. *et al*., 1982; Blumberg, M. S. and Lucas, D. E., 2000). However, while a role in maturation of motoneurones, motoneuronal axonal path finding, and contacts with skeletal muscles appears likely (Hanson, M. G. and Landmesser, L. T., 2004; 2006), their role in the CNS and for sensorimotor learning in particular has, however, not been known. The activity appears to be caused by spontaneous endogenous activity in neuronal circuits in the spinal cord and brain stem (Blumberg, M. S. and Lucas, D. E., 2000). Although present classifications tend to lump the spontaneous motility broadly into a few categories, detailed studies in humans distinguished 16 different types (De Vries, J. I. *et al*., 1982). The prevalence and complexity of these movements lead us to suggest that all major spinal motor systems contribute to the spontaneous movements during development. Furthermore, since somatosensory imprinting is

highly effective, it may well be that all major groups of spinal motor systems learn relevant aspects of the body anatomy and biomechanics during development by probing the sensory feedback after spontaneous endogenous activation. It has also been suggested that the sensory input arising after spontaneous movements guide the tuning of the somatotopic organization of the somatosensory cortex during development (Khazipov, R. *et al.*, 2004). It may thus be proposed that sensory input arising as a consequence of spontaneous movements during development plays a key role also in the organization of higher-order sensorimotor systems.

As yet, little is known about the molecular mechanisms underlying somatosensory imprinting. While calcium transients (Perrier, J. F. and Hounsgaard, J., 2000; Russier, M. *et al.*, 2003) and/or spontaneous fluctuations of glutamate release (O'Donovan, M. J. *et al.*, 1998; O'Donovan, M. J., 1999) have been suggested to play a role for the initiation of spontaneous movements, *N*-methyl-D-aspartate (NMDA) receptors may also be involved in the learning mechanisms since the rewiring of the tactile afferent fiber termination in the dorsal horn during development is blocked by topically applied MK-801 (Mendelson, B., 1994; Beggs, S. *et al.*, 2002; Granmo, G. *et al.*, 2002; 2005). Moreover, mice with a disturbed long-term potentiation (LTP) in the hippocampus exhibit disturbed receptive fields of NWR, suggesting that LTP-like mechanisms in the spinal cord may be involved in somatosensory imprinting (Thelin, J. M., 2005). To further unravel the mechanisms that underlie the somatosensory imprinting is clearly an important task in future.

5.12.5 Concluding Remarks

The embryonic development of the spinal cord is characterized by a ventral to dorsal temporal sequence. Appearance of motoneurons precedes that of interneurons which in turn precedes primary afferent ingrowth (Altman, J. and Bayer, S. A., 1984). It is thus of interest that there is a specific spatial relation between the topography of motoneuron pools and lamina V reflex encoders (Schouenborg, J. *et al.*, 1995) and between the weight distribution of cutaneous input to the dorsal horn and the receptive fields of the reflex encoders. Taken together, these findings indicate an instrumental role of motoneurons and the patterns of sensory feedback caused by spontaneous motility during development in the functional assembly of the dorsal horn. The elimination of inappropriate connections and strengthening of appropriate connections that normally occurs during development is likely to be a reflection of such a learning-dependent process.

Besides providing insights into how the wiring of the spinal cord is accomplished, the reviewed findings may well have clinical relevance. While the repair of the spinal cord after injury has so far been relatively unsuccessful, some advances indicate that regeneration across spinal lesions is possible and that some functional recovery may occur after such regeneration (Li, Y. *et al.*, 1997; Zgraggen, W. J. *et al.*, 1998; Levinsson, A. *et al.*, 2000). A major problem, once the obstacle of limited regeneration has been overcome, will be to eliminate the erroneous connections arising from regeneration (Bareyre, F. M. *et al.*, 2004). Such connections may be devastating for the patient. For example, patients with partially transected spinal cords often report chronic pain that is very difficult to alleviate (Sjölund, B. H., 2002). If adaptive mechanisms, such as somatosensory imprinting, which decrease the gain in erroneous connections and increase the gain in adequate connections can be utilized, true functional recovery may be attainable also from chaotically regenerated connections. A combination therapy based on training using feedback stimulation to tune the regenerated connections and pharmacological treatment that disinhibits regeneration might thus prove to be extremely useful.

Glossary

behavioral factors These factors refer to the specific behaviors of children, parents, and staff during pain episodes and also to parents' and children's broader actions in response to a chronic pain problem.

cognitive factors These factors include parents' and children's understanding of the pain problem, knowledge of effective therapies, and expectations for continuing pain or pain relief.

emotional factors These factors include parent's and children's feelings about the pain itself or responsible health condition and its adverse impact on the family, as well as any associated emotional disorders (such as anxiety or depression).

situational factors These factors represent a unique interaction between the child and the context in which the pain is experienced; they can vary dynamically, depending on the specific circumstances and setting.

5.13.1 Introduction

During the last two decades, unprecedented scientific and clinical attention has focused on the unique pain problems of infants, children, and adolescents (Schechter, N. L. *et al.*, 2003; McGrath, P. A., 2005; Schechter, N. L., 2007). Our knowledge of how children perceive pain and how we can alleviate their suffering has dramatically improved. Like adults, children's pain is modified both by ascending systems activated by sensory stimuli and by descending pain-suppressing systems activated by psychological factors. However, children's pain seems more plastic or modifiable in comparison to adults', so that environmental and psychological factors may exert a more powerful influence on children's pain perceptions (McGrath, P. A. and Dade, L. A., 2004).

Plasticity, from both a biological and a psychological perspective, is an essential concept in treating a child's pain. Our treatment approach has shifted from an almost exclusive disease-centered focus – detecting and treating the putative source of tissue damage – to a broader child-centered perspective, assessing the child with pain, identifying contributing psychological and contextual factors, and then targeting interventions accordingly. This chapter describes such a treatment approach, based on the unique factors that modify a child's pain.

5.13.2 Modifying a Child's Pain

Certain modifying factors are relevant for all children's pain experiences, irrespective of etiology. The model shown in Figure 1 lists the key factors that can increase pain, intensify distress, and exacerbate pain-related disability. A child's characteristics, such as cognitive level, sex, gender, temperament, previous pain experience, family, and cultural background (listed in the shaded box), generally shape how children interpret and cope with pain (Blount, R. L. *et al.*, 1991; Schechter, N. L. *et al.*, 1991; Bennett-Branson, S. and Craig, K., 1993; Schanberg, L. E. *et al.*, 1998; Chambers, C. T., 2003, Uman, L. S. and Chambers, C. T., 2007). However, other factors (listed in the open boxes) represent a

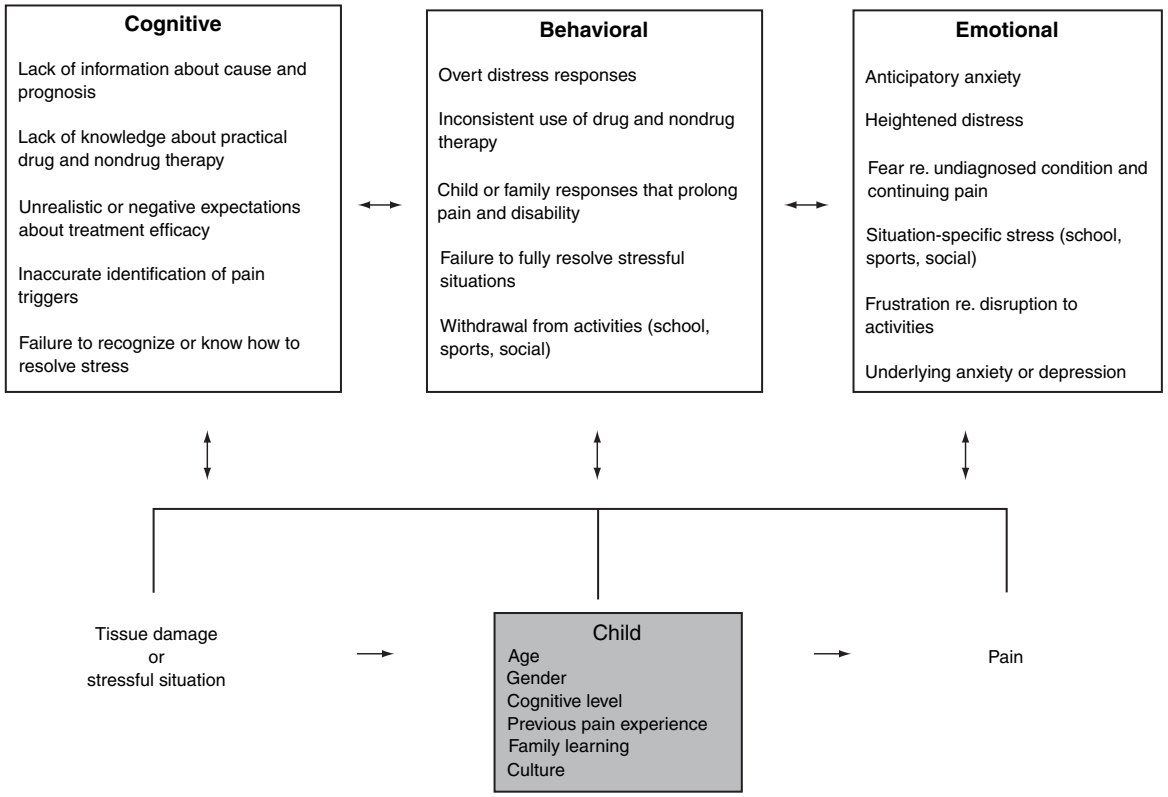

Figure 1 Biopsychosocial model for pain.

unique interaction between the child and the context in which the pain is experienced. These situational factors can vary dynamically, depending on the specific circumstances and setting. For example, a child receiving treatment for cancer may have repeated injections, central venous port access, or lumbar punctures, any of which can cause pain. Yet, even when tissue damage from these procedures is consistent, the situational factors present for a particular treatment are unique for each child.

The beliefs, behaviors, and emotional states of the children, parents, and clinicians all play important roles in modifying children's pain. Certain factors can intensify pain and distress, whereas others can eventually trigger pain episodes, prolong pain-related disability, or maintain the cycle of repeated pain episodes for children with recurrent pain syndromes (McGrath, P. A. and Hillier, L. M., 2003). While they may be unable to change the more stable child characteristics, health care providers can dramatically improve children's pain by modifying situational factors. Cognitive factors include parents' and children's understanding of the pain problem, knowledge of effective therapies, and expectations for continuing pain or pain relief. Behavioral factors refer to the specific behaviors of children, parents, and staff during pain episodes and also to parents' and children's broader actions in response to a chronic pain problem. Emotional factors include parent's and children's feelings about the pain itself or responsible health condition and its adverse impact on the family, as well as any associated emotional disorders (such as anxiety or depression). Parents' understanding of the cause of pain, possible treatments, and long-term prognosis guides their behaviors toward children and shapes children's emotional responses to the pain problem.

Situational factors may affect children even more than adults. Adults typically have experienced a wide variety of pains differing in etiology, intensity, and quality; their diverse experiences create a broad base of knowledge, realistic expectations, and versatile coping behaviors. In contrast, children, especially very young children, have considerably limited pain experience. They rely mainly on information conveyed within the immediate situation to interpret pain and to respond appropriately. Thus, children are particularly sensitive to environmental cues and to the behaviors of the adults who are present. A child's pain

is not predetermined by the extent of injury, disease progression, or invasiveness of a medical procedure. When health care providers ignore the powerful mediating impact of situational factors, they can easily, albeit inadvertently, increase a child's distress and pain. Generally, accurate information, realistic expectations, choices, control, and the use of some independent pain-reducing strategies will result in less pain.

5.13.3 Guidelines for Treating Acute Pain

Although distraction and parental support can minimize the pain caused by minor bumps and scrapes of childhood, pharmacological therapy (analgesics, adjunct analgesics, anesthetics, anxiolytics, and sedatives, as reviewed in other chapters) is the foundation for controlling children's acute pain (Finley, G. A. and McGrath, P. J., 2001; Dalens, B., 2003; Krane, E. J. *et al.*, 2003; Maunuksela, E.-L. and Olkkola, K. T., 2003; Yaster, M., 2003; Wilder, R. T., 2003; Brown, S. C. *et al.*, 2005; Bean-Lijewski, J. D., 2007; Schneeweiss, S., 2007). Children require appropriate analgesics, i.e., drugs selected according to type and severity of pain, doses determined by a child's weight based on the drug's duration of action to provide consistent pain relief and prevent breakthrough pain throughout the recovery period, and doses administered at regular dosing intervals. (For dosing guidelines, please see Finley, G. A. and McGrath, P. J., 2001; Krane, E. J. *et al.*, 2003; Brown, S. C. 2006.) Premature and term newborns show reduced clearance of most opioids (Wong, C. M. *et al.*, 2003). The differences in pharmacokinetics and pharmacodynamics among neonates, preterm infants, and full-term infants warrant special dosing considerations for infants and close monitoring when they receive opioids.

Recommended starting doses for analgesic medications for children are listed in Tables 1 and 2. Starting doses for adjuvant analgesic medications to control pain, drug-related side effects, and other symptoms are listed in Table 3.

Analgesics should be complemented by a practical cognitive-behavioral approach to ensure optimal pain relief, especially when treating acute pain from invasive medical procedures. First, health care providers should appreciate that children learn about pain because of their own injury-related acute pains. They perceive acute pains more as the occasionally inevitable result of daily activities than as something to fear. They quickly learn that pain is caused by injury, often easily visible, is relatively brief, and is relieved by many drug and nondrug interventions. Thus, they usually have accurate developmentally appropriate information about why something hurts and positive expectations for pain relief. In contrast, when children experience pain during invasive medical and dental procedures or after surgery, they often feel that they have no control, they may not know what to expect, and they may not know any simple pain control methods that they can use in these

Table 1 Nonopioid drugs to control pain in children

Drug	*Dosage*	*Comments*
Acetaminophen	10–15 mg kg^{-1} PO, every 4–6 h	Lacks gastrointestinal and hematological side effects; lacks anti-inflammatory effects (may mask infection-associated fever) Dose limit of 65 mg kg^{-1} day^{-1} or 4 g day^{-1}, whichever is less
Ibuprofen	5–10 mg kg^{-1} PO, every 6–8 h	Anti-inflammatory activity Use with caution in patients with hepatic or renal impairment, compromised cardiac function or hypertension (may cause fluid retention, edema), history of GI bleeding or ulcers, may inhibit platelet aggregation Dose limit of 40 mg kg^{-1} day^{-1}; maximum dose of 2400 mg day^{-1}
Naproxen	10–20 mg kg^{-1} day^{-1} PO, divided every 12 h	Anti-inflammatory activity. Use with caution and monitor closely in patients with impaired renal function. Avoid in patients with severe renal impairment Dose limit of 1 g day^{-1}
Diclofenac	1 mg kg^{-1} PO, every 8–12 h	Anti-inflammatory activity. Similar GI, renal, and hepatic precautions as noted above for ibuprofen and naproxen Dose limit of 50 mg dose^{-1}

Note: Increasing the dose of nonopioids beyond the recommended therapeutic level produces a ceiling effect, in that there is no additional analgesia but there are major increases in toxicity and side effects.
PO, by mouth; GI, gastrointestinal.
Brown, S. C. and McGrath, P. A. In Press. Pain Control in Children. In: Oxford Textbook of Palliative Medicine 4/e (*eds.* G. Hanks, N. Cherny, N. Christakis, M. Fallon, S. Kaasa, R. Portenoy). Oxford University Press.

Table 2 Opioid analgesics – usual starting doses for children

Drug	*Equianalgesic dose (parenteral)*	*Starting Dose IV*	*IV:PO ratio*	*Starting dose PO/ transdermal*	*Duration of action*
Morphine	10 mg	Bolus dose = 0.05–0.1 mg kg^{-1} every 2–4 h Continuous infusion = 0.01–0.04 mg kg^{-1} h^{-1}	1:3	0.15–0.3 mg kg^{-1} $dose^{-1}$ every 4 h	3–4 h
Hydromorphone	1.5 mg	0.015–0.02 mg kg^{-1} every 4 h	1:5	0.06 mg kg^{-1} every 3–4 h	2–4 h
Codeine	120 mg	Not recommended		1.0 mg kg^{-1} every 4 h (dose limit 1.5 mg $kg^{-1}dose^{-1}$)	3–4 h
Oxycodone	5–10 mg	Not recommended		0.1–0.2 mg kg^{-1} every 3–4 h	3–4 h
Meperidine[a]	75 mg	0.5–1.0 mg kg^{-1} every 3–4 h	1:4	1.0–2.0 mg kg^{-1} every 3–4 h (dose limit 150 mg)	1–3 h
Fentanyl[b]	100 μg	1–2 μg $kg^{-1}h^{-1}$ as continuous infusion		25 μg patch	72 h (patch)

[a]Avoid use in renal impairment. Metabolite may cause seizures.
[b]Potentially highly toxic. Not for use in acute pain control.
Principles of opioid administration:
1. If inadequate pain relief and no toxicity at peak onset of opioid action, increase dose in 50% increments.
2. Avoid IM administration.
3. Whenever using continuous infusion, plan for hourly rescue doses with short onset opioids if needed. Rescue dose is usually 50–200% of continuous hourly dose. If greater than 6 rescues are necessary in 24-h period, increase daily infusion total by the total amount of rescues for previous 24 h/24. An alternative is to increase infusion by 50%.
4. To change opioids because of incomplete cross-tolerance: if changing between opioids with short duration of action, start new opioid at 50% of equianalgesic dose. Titrate to effect.
5. To taper opioids – anyone on opioids over 1 week must be tapered to avoid withdrawal: taper by 50% for 2 days, and then decrease by 25% every 2 days. When dose is equianalgesic to an oral morphine dose of 0.6 mg kg^{-1} day^{-1}, it may be stopped. Some patients on opioids for prolonged periods may require much slower weaning.
PO, by mouth; IV, intravenous.
Brown, S. C. and McGrath, P. A. In Press. Pain Control in Children. In: Oxford Textbook of Palliative Medicine 4/e (*eds.* G. Hanks, N. Cherny, N. Christakis, M. Fallon, S. Kaasa, and R. Portenoy). Oxford University Press.
NOTE: Doses are for opioid-naive patients. For infants under 6 months, start at one-quarter to one-third the suggested dose and titrate to effect.

new situations. In fact, health care providers may instruct children how to cope (i.e., behave) during a painful procedure in a manner that makes it easier for the person administering the procedure, but does not necessarily make it better for the child.

Health care providers often focus on explaining to parents and inadvertently neglect the child. Time constraints necessitate juggling who has priority and, understandably, concerned parents are a priority. Yet, children should remain the number 1 priority because it is their pain that is directly modified. Every word and action conveys powerful information to children. As an example, a young boy became very distressed when he learned that a local anesthetic should freeze his arm so he wouldn't feel anything. Finally, he explained that he was afraid his arm would become like a Popsicle. Health care providers have tremendous power in influencing what children know, how they can respond, and the relevance of the situation (i.e., injury, disease, treatment) and consequent pain. The manner in which health care providers introduce themselves, the words they choose to explain what will happen, and whether they confidently show children what they could do to lessen the pain profoundly impact what children will experience.

These situational factors can intensify children's pain and distress, even when children receive anxiolytics and analgesics. As an example, when children with cancer at our center first started receiving topical anesthetic creams before intravenous insertions and portacather injections, considerably more children were referred to our pain clinic. We learned that busy clinical staff no longer focused on an individual child in the manner that they had previously – encouraging the child to understand from their specific perspective (i.e., age, gender, culture) and use their preferred 'close your pain gate' methods.

Table 3 Adjuvant analgesics – doses for children

Drug category	*Drug, dosage*	*Indications*	*Comments*
Antidepressants	Amitriptyline, 0.2–0.5 mg kg^{-1} PO.	Neuropathic pain (i.e., vincristine-induced, radiation plexopathy, tumor invasion, CRPS-1)	Usually improved sleep and pain relief within 3–5 days
	Titrate upward by 0.25 mg kg^{-1} every 2–3 days	Insomnia	Anticholinergic side effects are dose-limiting. Use with caution for children with increased risk for cardiac dysfunction
	Maintenance: 0.2–3.0 mg kg^{-1}		
	Alternatives: nortriptyline, doxepin, imipramine		
Anticonvulsants	Gabapentin, 5 mg $kg^{-1}day^{-1}$ PO.	Neuropathic pain, especially shooting, stabbing pain.	Side effects: gastrointestinal upset, ataxia, dizziness, disorientation, somnolence
	Titrate upward over 3–7 days. Maintenance: up to 15–50 mg $kg^{-1}day^{-1}$ PO divided TID.		Monitor for hematological, hepatic, and allergic reactions with carbamazepine
	Carbamazepine, initial dosing: 10 mg $kg^{-1}day^{-1}$ PO divided OD or BID. Maintenance: up to 20–30 mg $kg^{-1}day^{-1}$ PO divided every 8 h. Increase dose gradually over 2–4 weeks.		
	Alternatives: phenytoin, clonazepam		

(*Continued*)

Table 3 (Continued)

Drug category	*Drug, dosage*	*Indications*	*Comments*
Sedatives, hypnotics, anxiolytics	Diazepam, 0.025–0.2 mg kg^{-1} PO every 6 h.	Acute anxiety, muscle spasm	Sedative effect may limit opioid use. Other side effects include depression and dependence with prolonged use
	Lorazepam, 0.05 mg $kg^{-1}dose^{-1}$ SL	Premedication for painful procedures	
	Midazolam, 0.5 mg $kg^{-1}dose^{-1}$ PO administered 15–30 min prior to procedure; 0.05 mg $kg^{-1}dose^{-1}$ IV for sedation		
Antihistamines	Hydroxyzine, 0.5 mg kg^{-1} PO every 6 h.	Opioid-induced pruritus, anxiety, nausea	Sedative side effects may be helpful
	Diphenhydramine, 0.5−1.0 mg kg^{-1} PO/IV every 6 h		
Psychostimulants	Dextroamphetamine, methylphenidate, 0.1–0.2 mg kg^{-1} BID.	Opioid-induced somnolence	Side effects include agitation, sleep disturbance, and anorexia.
	Escalate to 0.3−0.5 mg kg^{-1} as needed	Potentiation of opioid analgesia	Administer second dose in afternoon to avoid sleep disturbances
Corticosteroids	Prednisone, prednisolone, and dexamethasone dosage depends on clinical situation (i.e. dexamethasone initial dosing: 0.2 mg kg^{-1} IV. Dose limit 10 mg. Subsequent dose 0.3 mg $kg^{-1}day^{-1}$ IV divided every 6 h)	Headache from increased intracranial pressure, spinal or nerve compression; widespread metastases	Side effects include edema, dyspeptic symptoms, and occasional gastrointestinal bleeding

CRPS-1, complex regional pain syndrome, type 1; PO, by mouth; IV, intravenous; SL, sublingual.

Brown, S. C. and McGrath, P. A. In Press. Pain Control in Children. In: Oxford Textbook of Palliative Medicine 4/e (*eds.* G. Hanks, N. Cherny, N. Christakis, M. Fallon, S. Kaasa, and R. Portenoy). Oxford University Press.

Instead, they applied the magic cream and sent children to a play area until it was time to conduct the invasive procedure. Despite the proven anesthetic properties of the cream, many children reported increased pain and exhibited increased distress in comparison to their pretopical procedures (McGrath, P. A., 1990).

Although psychological therapies are reviewed in other chapters, even the simple provision of information about what is happening, why the procedure is conducted in a certain manner, what equipment will be used, who will be present, the nature of the child's sensations during different phases of the procedure, and some straightforward instructions about how a child might lessen pain will dramatically reduce the pain caused by any invasive procedure to minimize anxiety and pain. As listed in Table 4, health care providers should explain what will happen and emphasize what sensations a child may feel, e.g., warmth, coolness, pressure, rather than the frightening label of pain. They should teach children a few basic attention and distraction methods to reduce pain and guide families to recognize the particular circumstances that exacerbate pain and distress.

Children who receive multiple invasive procedures over a prolonged period are at particular risk for developing anxiety and fear. Inaccurate understanding of the disease or injury, parents' anxiety about the underlying condition and painful treatments, inconsistency in treatment administration, lack of control and coping strategies, and fears about the effects of the disease or side effects of treatment can intensify a child's treatment-related pain. Regrettably, some inconsistencies in how procedures are conducted are common in clinical practice. The more procedures a child has, the more likely that they will experience a difficult procedure – more pain, more nausea, etc. A child then becomes fearful and expects that another difficult procedure is inevitable and a cycle of heightened anxiety, increased pain, and emotional distress ensues.

Many cognitive-behavioral programs have been designed to complement drug therapies for children with cancer (Hilgard, J. R. and LeBaron, S., 1984; LeBaron, S. and Zeltzer, L. K., 1996; Olness, K. and Kohen, D. P., 1996; Liossi, C., 2002; Collins, J. and Weisman, S. J., 2003; Kuttner, L. and Solomon, R., 2003). These child-centered programs usually combine basic education with psychological therapies (i.e., attention and distraction, hypnosis or hypnotic-like suggestions for analgesia, desensitization procedures, behavioral management, relaxation exercises, and biofeedback) to minimize children's anxiety and pain. The specific program components vary for different children because therapies are selected to target the unique child, family, and situational factors that were identified from the child's pain assessment as the factors that intensified children's pain, anxiety, and distress. Generally, as children receive developmentally appropriate accurate information, gain realistic expectations, have more choices and control, and use independent pain control strategies, they have less pain and distress.

5.13.4 Guidelines for Treating Chronic Pain

Effective treatment of chronic pain usually requires an integrated treatment approach comprising drug therapy, physical therapy, and psychological counseling, rather than a single therapy. Chronic pain generally has multiple sources affecting both peripheral and central nervous systems, with both nociceptive and neuropathic components. Certain cognitive, behavioral, and emotional factors may intensify pain, increase distress, and exacerbate a

Table 4 Preparing children for invasive procedures

Remember that anxiety and distress can increase pain.
Explain what will happen clearly, in simple developmentally appropriate language.
Emphasize the qualities of the sensations they may experience such as cold, sharp, tingling, and pressure so that children focus on what they are feeling, rather than only on the hurting aspect.
If the procedure will hurt, describe what children might feel using more familiar examples of pains that they have experienced during play and sports.
Use versatile pain control methods that involve children such as attention and distraction, deep breathing, counting exercises, or guided imagery.
Give children as many choices and as much control as possible such as choosing which arm for injections, whether to watch or look away, and which pain control method to use.

child's disability. The pain adversely affects all aspects of children's lives. Parents are distressed by the pain itself, its implications for their children's future, its life-threatening potential (if any), and the prospect of continuing pain and progressive disability. Parents and adolescents tend to emphasize and fear the future consequences of children's physical condition, whereas young children are more preoccupied by the immediate consequences and disruption to their daily activities. The dynamics within the family (both for siblings and for extended family members) inevitably change as chronic pain prevents children from pursing their normal activities and as family schedules adjust accordingly to the health care needs of the child with pain (for review, please see McGrath, P. J. and Finley, G. A., 1999; Berde, C. B. *et al.*, 2003; McGrath, P. A. and Dade, L. A., 2004).

In order to treat chronic pain effectively, health care providers should carefully determine the physical etiology (if possible) and also critically appraise the unique situational factors that may influence pain. Interdisciplinary teams, comprising physicians, nurses, psychologists, psychiatrists, and physical therapists, are better equipped to conduct a more comprehensive biopsychosocial assessment than a single pain specialist. After consultation among members, the team should provide a diagnosis that includes both the etiology and the relevant factors influencing children's pain. The biopsychosocial model shown in Figure 1 provides a concrete framework for explaining these factors and subsequently presenting the rationale for an integrated treatment approach comprising pharmacology, physiotherapy, and psychology. The specific drugs and therapies within this child-centered approach derive from the assessment results and are selected to target the responsible central and peripheral mechanisms and to mitigate the pain-exacerbating impact of situational factors.

NSAIDs and opioids in effective doses and regular dosing schedules can relieve pain with a primary nociceptive etiology. Drugs should be selected according to their analgesic potency based on the child's pain level – acetaminophen to control mild pain, codeine to control moderate pain, and morphine for strong pain (World Health Organization, 1998). Even when children require opioid analgesics, they should continue to receive acetaminophen (and NSAIDs, if appropriate) as supplemental analgesics. Health care providers should monitor a child's pain regularly and adjust analgesic doses as necessary to control the pain. The effective opioid dose to relieve pain varies widely among different children or in the same child at different times. To relieve ongoing pain, opioid doses should be increased steadily until comfort is achieved, unless the child experiences unacceptable side effects such as somnolence or respiratory depression. Adjuvant analgesics (especially gabapentin and tricyclic antidepressants) have become the main drugs for treating neuropathic pain (Berde, C. B. *et al.*, 2003).

Some children, irrespective of what may have caused their pain initially, develop significant functional disability that far exceeds their reported pain level. These children do not attend school, participate in sports, or socialize with peers. Families are frustrated because they may have tried to follow treatment recommendations and reintegrate children back into their normal activities. Parents may believe that health care providers do not believe the child and do not understand the severity of the pain problem. Families believe that children will return to normal (even when children have been disabled for years) as soon as health care providers cure the pain problem. A futile cycle ensues, with health care providers attempting to restore normal functioning and families refusing to cooperate until the pain is relieved. Children with severe disability constitute a unique clinical challenge. Gradually, I have learned to identify the problem to families as twofold – a chronic pain problem and a disability problem. Usually disability is the more serious problem. Thus, treatment should immediately focus on the both aspects – we must deal with the pain, but, concurrently, we must deal with the increasing disability. Almost all children who have a major disability problem will require additional psychological treatment and assistance to reenter school and resume their previous activities.

For any child with chronic pain, health care provides should recognize the common situational factors that influence parents' responses to children's continuing pain complaints, especially when pain is not caused by active disease or injury. Parents usually try to understand their child's pain from an acute disease perspective, where pain is due to a single cause and can be relieved by a single treatment. They do not understand that chronic pain, unlike most pains that they have already experienced, may have several interrelated causes. Thus, parents request further medical investigations as they search for the clear-cut physical etiology and concentrate on finding one treatment that will immediately stop the pain. Parents may reject potentially effective

treatments after only one attempt, even though the treatment would address some of the causes and might lessen children's pain over time. Some parents expect that their child will remain very disabled until the one right treatment is found and believe that they have no control in changing the future course of continuing pain and disability.

To mitigate the factors that can intensify a child's chronic pain or exacerbate disability, health care providers should "Stop, Look, & Listen": Stop an exclusive disease focus; Look at the big picture, i.e., assess the child with pain; and Listen to the child's pain history, appreciating the potential impact of situational factors (McGrath, P. A. and Dade, L. A., 2004). The diagnosis is a critical component of pain management. Even when some aspects of the pain condition are puzzling, health care providers should honestly describe what they know and explain what they need to explore further in a straightforward and reassuring manner. Accurate information about the pain source(s) can mitigate the increased distress caused by a family's misinterpretations and anxieties. Moreover, since expectancies can profoundly affect treatment effectiveness, health care providers should build on this knowledge and directly address their patients' expectancies within the diagnostic appointment.

An accurate diagnosis should include information about both the primary causes and the secondary contributing factors so that treatments can be targeted at each relevant factor. Since these factors may vary over time, pain assessment remains a critical component of any treatment regimen. The focus of continuing assessment is the child with pain – not only the pain features but also the situational factors that modulate pain. Even when pain is due to actively progressing disease such as for children with advanced cancer, many other factors can affect their pain and suffering. Health care providers should assess these factors and target treatments accordingly. The treatment rationale is on the multifactorial etiology of pain and recommendations for a multimodal treatment approach. This is in direct contrast to the single cause and single treatment approach normally adequate for relieving acute pain.

5.14.1 Introduction

Microarray gene chip technology is a powerful tool to evaluate changes in multiple transcript levels simultaneously in different tissue preparations. In the pain field, efforts have focused on characterizing gene transcript changes that occur in chronic pain states such as neuropathic pain (Wang, H. *et al.*, 2002; Xiao, H. S. *et al.*, 2002; Davis-Taber, R. *et al.*, 2003; Thimmapaya, R. *et al.*, 2003; Valder, C. R. *et al.*, 2003; Davis-Taber, R. *et al.*, 2004) and this will be the main focus of this chapter. Neuropathic pain is initiated or caused by a primary lesion or dysfunction of the nervous system. As this technology emerged, it was anticipated that it could be used to determine the key molecular players in both the development and maintenance of neuropathic pain, which would enhance our understanding of this disease and provide insights into the identification of potential therapeutic targets for the treatment of pain. Prior to microarray approaches, studies were limited to evaluation of a set of specific preselected genes/proteins in samples from animal pain models or human tissues using techniques such as quantitative reverse transcriptase polymerase chain reaction (RT-PCR), Western blot analysis, and immunocytochemistry. Dependent upon the gene chips used, this analysis permits evaluation of both known and unknown gene transcripts (expressed sequence tags (ESTs)) using relatively small amounts of RNA. In each of the studies highlighted in this chapter a wealth of transcriptional information was obtained. However, determination of which gene product would offer the best therapeutic potential will require extensive additional follow-up studies. Microarray studies are clearly just the starting point. This chapter will be divided into sections detailing the studies that have been reported evaluating gene expression changes from neuropathic pain models using microarray gene chip analysis, including discussion in each section on study design, sample selection, isolation of RNA, choice of microarray gene chip platforms, and data analysis. The follow-up to microarray studies outlining the expectations and limitations of these studies will also be described. Lastly, the use of microarray gene chips for pinpointing genetic variation in disease states that will direct suitable therapeutics based upon genetic predispositions for specific patient populations will be discussed.

5.14.2 Microarray Analysis of Whole Dorsal Root Ganglion from the Spinal Nerve Ligation Model

Several different studies have evaluated the expression changes that occur in the rat whole dorsal root ganglion (DRG; Wang, H. *et al.*, 2002; Thimmapaya, R. *et al.*, 2003; Valder, C. R. *et al.*, 2003) and dorsal horn of the spinal cord (Sun, H. *et al.*, 2002; Wang, H. *et al.*, 2002) following spinal nerve ligation (SNL) using microarray analysis. The overall goal of each of these studies was to obtain a better understanding of the molecular pathophysiology of neuropathic pain and through this analysis identify potential new targets for the treatment of this chronic pain state. In some studies following tight ligation of the lumbar 5 (L5) and

lumbar 6 (L6) DRG, the development of allodynia was shown to develop 3 days following surgery and remained established for weeks ipsilateral to the insult (Wang, H. *et al.*, 2002; Valder, C. R. *et al.*, 2003). In these studies each animal was assessed for the development of tactile allodynia by behavioral testing prior to being included/excluded from the study. This was performed using von Frey filaments and to be included in the study animals needed to have a paw withdrawal threshold of less than 3 g in the neuropathic rats and greater than 10 g in the control rats. While some studies focused on evaluating the changes that occur both during the development and in fully established neuropathic pain (Wang, H. *et al.*, 2002), others assessed only established pain (Sun, H. *et al.*, 2002; Thimmapaya, R. *et al.*, 2003; Valder, C. R. *et al.*, 2003; Davis-Taber *et al.*, 2003). Several experimental design differences exist in each of these reports. In some studies since the contralateral paw did not display significant allodynia similarly to the sham animals, the L4/L5/L6 (Wang, H. *et al.*, 2002) or L5/L6 (Valder, C. R. *et al.*, 2003) DRG contralateral to the injury were selected for comparison with the equivalent injured DRGs from the same animals. In a parallel study to avoid any potential issues that could arise during surgery to alter gene expression contralateral to the injury and not revealed by allodynia assessment, the L5/L6 ipsilateral to the surgery were compared with the L5/L6 from sham-operated animals (Thimmapaya, R. *et al.*, 2003).

Another interesting comparison examined the expression differences between the injured L5/L6 DRG from Harlan and Holtzman Sprague-Dawley rats (Valder, C. R. *et al.*, 2003). The Holtzman rats were selected for this analysis as they do not develop the tactile allodynia observed in Harlan rats following SNL (Luo, Z. D. *et al.*, 1999). The goal of this study was to compare the expression profiles between these two strains and then extend these analyses to assess changes that were regulated following injury in one or both strains. This study did identify differentially expressed genes in the two strains, providing new information on neuroplasticity in DRG of these rats in response to nerve injury (Valder, C. R. *et al.*, 2003) in addition to those associated with neuropathic pain. However, cautious analysis of these data is important since similar regulation of gene changes in both strains is not an eliminating factor in defining whether the altered gene transcript is related to neuropathic pain development. Several transcripts that are known to be centrally involved in pain processing did change in both strains, that is, Nav1.8 and protein kinase C epsilon highlighting the limitations of this study.

A critical consideration when designing these experiments is to ensure that sufficient samples are collected to reflect the true changes that arise due to neuropathic pain and animal variation accurately. To this end assessment of DRG from L5/L6 region was performed using at least ten animals that were pooled prior to isolation of RNA for each of these studies. The comparison was made between the injured L5/L6 and either the contralateral L5/L6 (Wang, H. *et al.*, 2002) or sham L5/L6 (Thimmapaya, R. *et al.*, 2003). In one of the spinal cord studies nine animals were divided into three groups and in each group the dorsal and ventral spinal cords were pooled separately to form each pair of samples (three pairs). The comparison that was made in this tissue was between the dorsal and ventral spinal cord of neuropathic rats (Wang, H. *et al.*, 2002). In the other study, the global gene expression in the ipsilateral lumbar spinal cord was compared with the contralateral lumbar spinal cord from the neuropathic rats and to the sham control (Sun, H. *et al.*, 2002).

Typically protocols for isolating total RNA have been comparable throughout these studies using the TRizol protocol (Life Technologies/Invitrogen; Carlsbad, CA, USA) followed by RNeasy (Qiagen; Valencia, CA, USA) RNA clean-up step. The RNA quality was assessed either by denatured gel electrophoresis or capillary electrophoresis on the Agilent 2100 Bioanalyzer (Applied Biosystems; Foster City, CA, USA) to ensure that the 28S:18S ribosomal RNA (rRNA) ratio was greater than 1.0 for each sample, indicating that the sample was pure.

The microarray gene chip platform that was selected for each of these studies was the Affymetrix rat RG-U34a GeneChip®. On these microarray chips, each gene transcript is represented by probe sets containing 16 oligonucleotides, eight of which are matched and eight mismatched to the sequence of the transcript of interest. The oligonucleotides are 20 base pairs long, with a 3′ bias and may be to the coding and noncoding regions of the gene. Hybridization probes from each of these samples were generated and hybridized to the chips as recommended by Affymetrix. The microarray data was analyzed using the SAFER algorithm (Holder, D. *et al.*, 2002), Microarray Suite Expression Algorithm (Affymetrix; Santa Clara, CA, USA) or Rosetta Resolver (Rosetta Biosoftware; Seattle, WA, USA). Several microarray analysis software packages are available. Some utilize only a statistical algorithm (Affymetrix analysis software) while other analysis packages incorporate error models for normalization

of intensity between arrays and adjustments for probe-specific biases (SAFER and Resolver). Following a paired *t*-test and analysis of variance (ANOVA) analysis to determine a ratio for the expression changes between both samples a *P* value is generated and represents the probability that an observed gene expression change was due to a measurement error. To be considered significant, the change in gene expression had to occur in each microarray experiment and had to exhibit a value of $P \leq 0.05$ within each experiment. Another consideration that has been shown in each of these studies is how much does the transcript need to change to be considered significant enough to play a role in pain? In all the studies discussed in this chapter a cut-off of twofold was selected. This arbitrary cut-off was chosen since a large number of significant changes were observed but it is known that the expression of $P2X_3$, a validated pain target, only changed by 1.8-fold and would be excluded from this analysis. Therefore it is important not to exclude all small changes due to magnitude but if their changes are significant with $P \leq 0.05$, further analysis is warranted.

5.14.3 Microarray Data Analysis and Follow-up Studies

Following microarray analysis, the changes that were observed must be confirmed using either quantitative RT-PCR (Q-RTPCR), *in situ* hybridization, or, if reagents are available, immunocytochemistry. The latter two are preferable as the microarray studies described so far have all examined heterogeneous populations of cells (neurons and glial cells) and evaluation of specific tissue sections would provide a more precise profile of where the expression changes have occurred. Following confirmation of a subset of transcripts identified by microarray, data analysis has focused on classifying the gene transcripts into groups based upon the function of the gene product if known. An example of such a classification comes from the studies examining the changes in the L5/L6 DRG following SNL compared to sham L5/L6 DRG whereby gene products were grouped into cellular homeostasis and remodeling, ion channels and receptors, enzymes, immune response, neuronal markers, synaptic plasticity, transcription factors, and a miscellaneous category (Thimmapaya, R. *et al.*, 2003). Following this classification, it became evident that several examples of genes involved in synaptic plasticity (e.g., Narp and synaptobrevin) were downregulated, whereas genes involved in the immune response (e.g., MHCII) and cell regeneration/proliferation (e.g., Reg-2 and GADD45) were upregulated. A similar pattern of changes has been observed in the different neuropathic pain studies reported (Wang, H. *et al.*, 2002; Xiao, H. S. *et al.*, 2002; Valder, C. R. *et al.*, 2003).

5.14.4 Microarray Analysis of Subpopulations of Neurons Isolated from Dorsal Root Ganglion

All the studies described above examine the gene changes that occur in the entire DRG, which is composed of heterogenous subpopulations of cells (neurons and glial cells). Examining specific subpopulations of neurons would provide more precise information on the transcript expression changes. To accomplish this, LCM was used. This is a novel technology that permits the isolation and capture of specific cells from a tissue such as DRG in a native state. Determining the gene expression profile of different cell types has been hampered until recently by the inability to recover enough high-quality RNA from these cells for use in microarray experiments. Application of a new technique, antisense RNA (aRNA) amplification, has increased the yield of RNA to accommodate the requirements necessary for complementary DNA (cDNA) spotted and high-density oligonucleotide microarrays. DRG are composed of multiple neuronal and glial cell types and in particular, small-diameter neurons mediate nociceptive responses whereas large neurons facilitate mechanosensation. Two studies have profiled the differential gene expression of these nociceptive and mechanosensitive naive neurons by microarray (Luo, L. *et al.*, 1999; Davis-Taber, R. *et al.*, 2003). DRGs were flash frozen in cryomolds, sectioned to ~8 μm thickness and visualized with a Nissl (cresyl violet) stain to identify the neurons. Naive small (<25 μm and an identifiable nucleus) and large (>40 μm) diameter neurons were captured (PixCell II LCM system; Arcturus, Mountain View, CA, USA) and total RNA extracted from cellular material adherent to the thermoplastic film on the LCM caps. Multiple RNA isolation and amplification reagents and kits are commercially available from a variety of vendors (e.g., Arcturus, Mountain View, CA, USA; Stratagene, San Diego, CA, USA; Epicentre Technologies, Madison, WI, USA). aRNA was amplified two to three times prior to

hybridization onto a custom cDNA spotted array or an Affymetrix high-density oligonucleotide GeneChip® array (Luo, L. *et al.*, 1999; Davis-Taber, R. *et al.*, 2003).

There are several aspects of experimental design that should be considered prior to initiation of an LCM microarray study. First, a sufficient number of cells should be captured. For each of the LCM studies discussed, approximately 1000 small and 1000 large DRG neurons were isolated for microarray profiling. An alternative to capturing a greater amount of cellular material is increasing the number of rounds of RNA amplification. One trade-off to higher yields is a shortening of the RNA transcripts with each successive round of amplification. One other consideration is the 3′ bias of the aRNA transcripts generated. This is important when determining the microarray platform to use. Many high-density oligonucleotide arrays already incorporate a 3′ bias in their probe design (e.g., Affymetrix) but this issue may be more significant when using custom spotted arrays.

The initial studies profiling naive small and large DRG neurons observed a differential gene expression pattern for these two neuronal subpopulations. In the first study, naive cervical DRG aRNA from adult rats were hybridized to a custom cDNA spotted microarray (Luo, L. *et al.*, 1999). The microarray chip had 477 cDNAs that were obtained from two differential display experiments: (1) identified genes uniquely expressed in DRG compared to brain, liver, and kidney; and (2) genes that were differentially expressed in L5/L6 between ipsilateral (SNL) and contralateral (control). Approximately 40 genes were found to be enriched in either neuronal subpopulation with a greater majority detected in the small DRG neurons. The second study collected similar sized neuronal cells from rat lumbar L5/L6 DRG and hybridized the aRNA to the Affymetrix Neurobiology GeneChip® (Davis-Taber, R. *et al.*, 2003). In the small and large DRG neurons, ∼100 genes were detected and classified into functional groups (channels and receptors, enzymes, cell signaling, and cytoskeletal). In the categories of cell signaling and channels and receptors, there was an equal number of genes differentially enriched in each neuronal subpopulation, however, large DRG neurons predominantly expressed cytoskeletal proteins and enzymes. Examining the results reported in both experiments has shown that similar expression patterns and fold enrichment were observed for both neuronal subpopulations. A lack of glial-specific gene expression suggests that there was minimal glial contamination in the capturing process.

To understand the gene expression changes that occur in neuropathic pain states further, neuronal subpopulations were isolated from DRG following SNL or sham surgery and profiled by microarray. Similar to the naive DRG studies, small (∼1000 cells) and large (∼1000 cells) neurons were captured from SNL and sham L5/L6 ipsilateral DRGs (∼4000 total) by LCM and evaluated by Affymetrix rat RG-U34a GeneChip® arrays (Davis-Taber, R. *et al.*, 2004). Microarray analysis showed altered expression patterns between SNL and sham animals especially in large DRG neurons where the majority of gene changes occurred. Although some genes showed a common expression signature across both small and large neurons, a number of genes were dysregulated in only one neuronal subtype. A comparison of the whole DRG SNL microarray data (Thimmapaya, R. *et al.*, 2003) with the SNL small and large DRG neuron study revealed only a small number of genes that were commonly altered in all three samples. Also, only a small percentage of gene expression changes observed in the small (35%) or large (22%) neurons were dysregulated in the whole DRG microarray study. This suggests that within the individual neuronal subtypes, the distinct expression patterns that were observed may have been masked or minimized in the whole DRG microarray study. Microarray analysis of the small and large DRG neuronal subpopulations isolated from the injured DRG following SNL has provided a deeper understanding of the differential gene expression associated with neuropathic pain (Davis-Taber, R. *et al.*, 2004).

A potential limitation of the LCM microarray studies is the ability to collect a pure subpopulation of neurons. The time constraints of standard immunohistochemical staining procedures would allow tissue sections to rehydrate which could hinder precise capture of individual cells so a modified cresyl violet staining protocol developed by Arcturus Engineering, Mountain View, CA, USA, was used to visualize both small and large diameter DRG neurons. Without a way to distinguish the different small DRG neuron subtypes, a mixed population of peptidergic and non-peptidergic neurons were captured and pooled together. TRPV1 expression is an example of this limitation whereby it was shown to be downregulated in the L5/L6 small DRG neurons in the LCM SNL study but was not detected in the naive, L5/L6 small DRG neurons. Localization studies have shown that TRPV1 is found on peptidergic small-diameter

neurons and the receptor's inconsistent detection may result from the level of sensitivity of RNA amplification and microarray techniques from a mixed population of small DRG neurons. However, evaluation of the expression levels of RNA from subpopulations of neurons has provided a depth of information on transcripts that was previously not possible when whole DRG samples were assessed.

5.14.5 Evaluation of Additional Neuropathic Pain Models by Microarray

In addition to studies on the expression changes in DRG from SNL model of neuropathic pain, microarray analysis has also been performed on DRG following peripheral axotomy. In one study a custom microarray chip was generated that contained genes that were overexpressed in DRG 14 days following axotomy (Xiao, H. S. *et al*., 2002). The L4/L5 DRG were then probed against this chip at various timepoints to assess the changes in expression that occur both during the development and following established pain. Some genes changed expression immediately by day 2 (neuropeptide Y, heat shock protein 27, LIM domain protein CLP36) while others showed a more significant change at 14 days (neuronal nitric oxide synthase (nNOS), calcitonin gene-related peptide (CGRP)) following axotomy. The changes were confirmed for a subset of genes by *in situ* hybridization. Interestingly many of the genes that changed expression were the same as those observed in the SNL model (Table 1) indicating that these neuropathic pain models share some underlying molecular components. A second study used the Affymetrix rat RG-U34a GeneChip® gene chip and also examined the L4/L5 DRG following sciatic nerve axotomy over a time course of 1–14 days postinjury (Costigan, M. *et al*., 2002). This

Table 1 Representative gene expression changes identified by microarray analysis from rat L5/L6 DRG following peripheral nerve injury

Accession number	*Description*	*SNL (L5/L6) (Thimmapaya, R. et al., 2003)*	*Published changes: preclinical neuropathic models*
X59864	ASM15	4.84	↑ Valder C. R. *et al*. (2003)
AI009268	Ca^{2+}/calmodulin-dependent protein kinase 2 delta	2.29	↑ Xiao H. S. *et al*. (2002)
X81193	Cysteine-rich protein 3 (muscle LIM protein)	42.57	↑ Wang H. *et al*. (2002); ↑ Xiao H. S. *et al*. (2002); ↑ Valder C. R. *et al*. (2003)

X52772	Synaptotagmin I	−3.03	↔ Xiao H. S. *et al*. (2002)
X59737	Ubiquitous mitochondrial creatine kinase	−6.33	↓ Wang H. *et al*. (2002)

Genes that show enhanced or diminished expression from injured dorsal root ganglia (DRG) versus sham-operated DRG with a twofold change and $P \leq 0.05$. The fold increases and decreases in gene expression observed with DRG from spinal nerve ligated (SNL) rats are given, together with published microarray analysis of gene changes from preclinical neuropathic pain models (Xiao, H. S. *et al*., 2002, axotomy; Wang, H. *et al*., 2002, SNL; Costigan, M. *et al*., 2002, axotomy; Valder, C. R. *et al*., 2003, SNL). Genes were upregulated (↑), downregulated (↓), or unchanged (↔).

analysis compared naive DRG to the injured DRG and focused on the evaluation of data following this comparison. The data presented supported the use of a $P < 0.05$ significance threshold for detecting regulated genes. When a cut-off of a twofold change in expression was applied to select gene transcripts to assess, this led to an estimated error rate of 16%. Combining a more than 1.5-fold expression change and a $P < 0.05$ reduced the estimated error to 5%. Using the latter analysis, 240 genes changed expression significantly and many had not been previously described as changing following axotomy. Changes in expression of a subset of the genes were confirmed by *in situ* and Northern blots analysis. This study also identified increases in gene expression of genes mostly involved in immune responses and inflammation and decreases in those involved in neurotransmission similar to that reported for the SNL model of neuropathic pain. Taken together the microarray studies identified genes that are dysregulated in neuropathic pain states from different pain models providing an opportunity to unveil potential neuropathic molecular signatures that are common between these models.

5.14.6 The Strengths and Limitations of Microarray Analysis for Pain Research

Our knowledge of the complexity of neuropathic pain has heightened following the use of microarray gene chip technology. This approach provided opportunities to examine multiple gene transcripts simultaneously in pain states. Interestingly in these different studies similar gene changes have been observed in the DRG from diverse peripheral nerve injury models. A subset of these changes are given in Table 1, which shows that in most cases the gene products were dysregulated in a similar direction. However, in a couple of examples the transcripts were altered differently between the different models (Nell1; protein kinase C epsilon). The studies that have been performed have focused on gene changes that occur in the spinal cord and DRG but it is also known that areas of the brain are important for pain processing. Changes in gene expression can also occur in brain areas such as the rostral ventral medulla and periaqueductal gray, which participate in ascending and descending nociceptive signaling (Miki, K. *et al.*, 2002) in chronic pain states.

In addition to the strengths of microarray analysis detailed above there are also limitations. These assays are not suitable for detection of post-translational modifications of functional proteins including phosphorylation/dephosphorylation of ion channels, membrane proteins, and transcription factors. Functional modifications of pain-relevant proteins that do not alter their transcriptional levels include activation of *N*-methyl-D-aspartate receptors by injury-induced protein kinase C-mediated phosphorylation (Chen, L. and Huang, L. Y., 1992) and the downstream regulatory element antagonistic modulator (DREAM)-mediated derepression of prodynorphin expression that is regulated by elevated intracellular calcium and protein kinase A activation (Carrion, A. M. *et al.*, 1998). DREAM-deficient mice have been shown to have elevated spinal cord prodynorphin levels and reduced inflammatory pain behaviors (Cheng, H. Y. *et al.*, 2002).

Additionally, translation of the data arising from these studies to identify potential novel therapeutic targets is also a challenge. The approach undertaken in the studies highlighted in this chapter, has been to examine the literature for any data that would indicate that the protein encoded by a dysregulated transcript plays a role in pain. A complicating factor studying nociception and associated gene regulation in pain states is that unlike metabolic diseases where pathways are well understood, little is known about the specific pathways underlying pain. Application of programs that assess gene ontology (i.e., GenMAPP, GoSurfer, GOTM, WebGestalt, GoMiner, OntoExpress, and ErmineJ) and known pathways (i.e., Pathway Assist) can provide some insights into nociceptive signaling.

As mentioned earlier, microarray studies have generated a wealth of information but to understand the role of each gene product in pain will require extensive follow-up studies. Another approach that could be taken would be to evaluate the effects of administering target specific agonists or antagonists in preclinical pain models to determine if these proteins offer potential opportunities for novel therapeutic intervention if such agents already exist. Gene silencing using antisense or small interfering RNA (siRNA) approaches would also be other ways to establish if a protein that was dysregulated in a pain state would be a useful pain target (Hemmings-Mieszczak, M. *et al.*, 2003; Tan, P. H. *et al.*, 2005). Pain microarray studies as predicted have deepened our understanding of key players in neuropathic pain. However, deciphering the precise role of specific gene products in pain and identification of novel therapeutic targets awaits further investigation and is eagerly anticipated.

5.14.7 The Genetics of Pain

The pain microarray gene chip analysis detailed earlier in this chapter provides a snapshot of the changes in gene expression that occur in chronic pain states with the ultimate goal of understanding pain mechanisms and identifying potential novel therapeutic targets for pain treatment. Additional efforts to identify human genes associated with pain have examined congenital insensitivity to pain (CIP) that has been linked to the gene encoding serine palmitoyl-transferase (Nagasako, E. M. *et al.*, 2003). A subtype of this disorder CIP IV has been linked to single changes in nucleotide sequence (single nucleotide polymorphisms (SNPs)) of the TrkA receptor rendering the protein nonfunctional (Indo, Y. *et al.*, 1996). While nerve growth factor binding to the TrkA receptor is known to contribute to the survival and regulation of small diameter neurons, loss-of-function phenotypes observed in these individuals with SNPs are similar to the knockout animals. Another example is the gene responsible for familial hemiplegic migraine that has been linked to human chromosome 19p13 and more recently identified as the gene encoding a calcium channel α-subunit (CACNA1A; Joutel, A. *et al.*, 1993). Specific patients suffering from migraines have been shown to have missense mutations in this gene that lead to gain-of-function phenotypes. This calcium channel has been shown to be associated with serotonin release, magnesium levels, and the phenomenon of cortical spreading depression, each of which contribute to the pathophysiology of migraine (Ophoff, R. A. *et al.*, 1996).

Differences in human pain perception have also been associated to a common SNP (V158M) in the gene of the enzyme catechol-*o*-methyltransferase (COMT). Individuals homozygous for the Met^{158} allele of COMT showed diminished regional μ-opioid responses to pain compared with heterozygotes, which was opposite to the effects observed with the Val^{158} homozygote (Zubieta, J. K. *et al.*, 2003). Individuals with the more active form of the enzyme (Val^{158}) are less susceptible to pain than people with Met^{158} at the same position. COMT activity is also associated with a pathological pain condition known as temporomandibular joint disorder (TMD) that impacts 5–15% of the adult population. The relationship between COMT polymorphism, pain sensitivity, and risk of TMD development has recently been reported (Diatchenko, L. *et al.*, 2005). Three genetic variants (haplotypes) of the COMT gene, designated as low-pain sensitivity, average-pain sensitivity, and high-pain sensitivity were identified, that encompass 96% of the examined genotypes and lead to altered enzyme activity. The more active the COMT enzyme inversely correlated with pain susceptibility and the lower risk of developing TMD (Diatchenko, L. *et al.*, 2005).

Another interesting aspect of human genetics examined the sex differences in pain and analgesic sensitivity has been an area of research focus and increasing amounts of evidence suggest that sex differences may reflect the activation of gender-specific neural mechanisms. Since clinically κ-opioid receptor agonists show more efficacy in women than men, a recent report investigated the possible sex specificity of the genetic mediation of κ-opioid analgesia in mice using quantitative trait locus (QTL) mapping (Mogil, J. S. *et al.*, 2003). QTL mapping is a technique in which the co-inheritance of continuous traits and polymorphic DNA markers (e.g., microsatellites or SNPs) can be used to broadly identify the chromosomal location of genes responsible for trait variability (Lander, E. S. and Schork, N. J., 1994). Three convergent lines of evidence point to the mouse melanocortin-1 (*MCR1*) gene as the female-specific QTL. Furthermore analysis of women with red hair and fair skin containing two variant *MCR1* alleles displayed significantly greater analgesia from the κ-opioid pentazocine than all other groups (Mogil, J. S. *et al.*, 2003).

With the completion of the human genome project and ongoing efforts to sequence the genomes of a variety of other species, a plethora of sequence information is now available. New microarray applications and chip platforms are being developed to pinpoint genetic variation in disease states, isolate biomarkers that may indicate a predisposition for a given disease and identify treatment strategies and/or drug candidates that would have maximal benefit for a patient population with a specific genetic make-up.

The first of these new array platforms are comparative genomic hybridization (CGH) arrays. These microarrays are designed across large areas of sequence (i.e., a single chromosome) and even an entire genome to provide broad coverage for genotyping. CGH arrays have been generated from bacterial artificial chromosome (BAC) clones containing large genomic inserts and require a reference genome for comparison to the sample genome (Herr, A. *et al.*, 2005). These arrays have been used to determine differences in copy number

of particular genes and identify chromosomal imbalances found in cancer, genetic disorders, and deletion mutants with unique phenotypes used for scientific research (Hughes, T. R. *et al.*, 2000; Bruder, C. E. G. *et al.*, 2001; Herr, A. *et al.*, 2005). In contrast, to CGH arrays, resequencing and genome tiling arrays are designed to smaller, specific regions of a chromosome or genomic sequence and have been used to detect unknown mutations or to narrow down the area where a mutation may occur (Chee, M. *et al.*, 1996; Galvin, P. *et al.*, 2004; Lin, S. M. *et al.*, 2006). Resequencing arrays have probes designed to a particular sequence which when combined together will encompass all of the sequence within a specified region. Tiling arrays are designed to walk along a section of sequence with each probe representing one of the four nucleotides at a single nucleotide position. The probes are designed in sets of four. At a certain nucleotide position in the middle of the probe, each of the four probes will represent a different nucleotide (A, C, G, or T). The next four overlapping probes will have a mismatch (A, C, G, or T) at the next nucleotide position in succession from the mismatch in the previous probe set. The overall result from both these array platforms is a lack of hybridization and a subsequent decrease in signal intensity for the probes surrounding a mutation or polymorphism.

Linkage analysis studies using restriction-fragment length polymorphisms (RFLP) and polymorphic microsatellites have been useful in understanding mendelian-linked diseases. However, these tools have proven less consistent for mapping more complex disorders (i.e., schizophrenia, manic depression, and multiple sclerosis) that may have greater genetic heterogeneity or nonmendelian inheritance (Risch, N. J., 2000). More recently, SNPs, single nucleotide changes in DNA sequence, have been identified and catalogued in a number of genomic databases. Several SNP microarray chips have been developed (e.g., Affymetrix GeneChip Human Mapping 10K array) and used in concert with high-density microsatellite linkage sets to identify susceptibility or candidate genes that may be associated with the phenotype of a specific disease (Riley, J. H. *et al.*, 2000; Risch, N. J., 2000; Roses, A. D., 2000; Sawcer, S. J. *et al.*, 2004; Schaid, D. J. *et al.*, 2004).

Microarray can be a powerful tool, but also a hindrance. This technology can quickly and efficiently generate large amounts of data. However, excavating through this mass of information can be a time-consuming and possibly fruitless process without the proper analysis tools. With the implementation of these new array platforms, software has also been designed to aid in genotyping and linkage mapping studies. In the future, microarray may deepen our understanding of the genomic landscape and perhaps shed light on the origins of disease states. This genetic-driven trend could lead to individualized medical diagnoses and therapeutic treatment strategies.

Glossary

CREB Ca^{2+} and cAMP response element-binding protein, a transcription factor that binds to specific enhancer elements in DNA and enhances the expression of corresponding genes when certain Ca^{2+}- or cAMP-activated protein kinases, such as CaMK or PKA, phosphorylate the CREB protein.

degenerin/epithelial Na^+ (DEG/ENaC) channels A family of ion channels that conduct Na^+ ions and can be constitutively active or gated by mechanical distention or protons. Channels that are gated by protons are called acid-sensing ion channels (ASICs).

MAPK (ERK) Mitogen-activated protein kinase, a family of protein kinases that includes the extracellular signal-regulated kinase (ERK). ERK has many functions related to neural plasticity, both in the cytoplasm and nucleus.

MRG Mas-related genes, a family of genes encoding G-protein-coupled receptors, some of which are expressed selectively in mammalian nociceptors. Also called sensory neuron-specific G-protein-coupled receptors (SNSRs).

NMDA-receptor-dependent LTP *N*-Methyl-D asparate-receptor-dependent long-term synaptic potentiation, a form of use-dependent synaptic plasticity induced by Ca^{2+} influx through the class of glutamate receptors that is selectively activated (pharmacologically) by the drug, NMDA.

RFamide peptides A family of peptide neurotransmitters sharing the same C terminal RFamide (arginine-phenylalanine-NH_2) sequence.

transient receptor potential (TRP) A family of ion channels, many of which conduct cations nonselectively. Different channels in this family are opened by various inputs, including heat, cooling, protons, and intracellular signals.

TTX-resistant, voltage-gated Na^+ channels Members of the voltage-gated Na^+ channel family that are relatively insensitive to blockade by the specific antagonist, tetrodotoxin (TTX). These channels (NaV1.8 and NaV1.9) are expressed selectively in nociceptive dorsal root ganglion neurons.

5.15.1 Introduction

Pain, according to a widely accepted definition (Merskey, H. and Bogduk, N., 1994), is an unpleasant sensory and emotional experience associated with actual or potential tissue damage. This definition is intended to capture essential features of human experiences linked to tissue damage and makes no claims about the evolutionary roots or possible biological functions of pain. Nonetheless, it raises two distinct sets of evolutionary questions. First, how did sensory responses to actual or potential tissue damage evolve? What biological adaptations do these responses represent, and to what extent are the underlying mechanisms conserved across the animal kingdom? Second, how did the unpleasant emotional components of pain evolve? This essay considers comparative functional and molecular findings from diverse species in the animal kingdom that begin to address these questions. Because this task requires reference to far more reports than can be cited in a brief account, citations are made primarily to review articles or to recent reports that provide additional references to this diverse literature. Although no recent, comprehensive review of nociceptive biology in invertebrates exists, highly comprehensive reviews of nociceptive mechanisms in mammals can be found in other chapters in this volume, and in a recent book (Willis, W. D. and Coggeshall, R. E., 2004).

5.15.2 Evolution of Nociceptive Mechanisms

Because an animal's reproductive success is clearly enhanced if it can detect and avoid pervasive threats to its structural integrity that otherwise would impair or end its ability to reproduce, selection pressures for mechanisms that recognize noxious stimuli and trigger adaptive physiological and behavioral responses must be very strong (Walters, E. T., 1994). Indeed, animals in several phyla have now been shown to possess nociceptors connected to neural networks controlling defensive responses, and these varied nociceptive systems share numerous features including distinctive forms of plasticity. Common properties in diverse species are of interest for evolutionary questions because they point to (1) common selection pressures that have shaped similar but independently derived (analogous) adaptations; and/or (2) the conservation of homologous mechanisms descending from common ancestors. Figure 1 shows a simplified view of evolutionary relationships among selected species mentioned in this essay that have been used to study nociceptive biology. Those that have had their genome completely sequenced are indicated by asterisks (human, mouse, fruit fly, and roundworm). The current explosion of molecular genetic information from a growing number of species promises to illuminate evolutionary relationships among nociceptive mechanisms with a level of detail and precision that could only be dreamed of a few years ago.

5.15.2.1 Nociceptors

Nociceptors are defined as sensory neurons that are activated preferentially by tissue-damaging stimuli, either immediately or when a noxious stimulus is sufficiently prolonged. Because of the medical, social, and economic importance of pain, most studies of nociceptors have been in selected mammalian species rather than animals more distantly related to humans. Thus, the comparative physiological and molecular information needed to discern evolutionary patterns in nociceptive function is still quite limited. However, the availability of extensive genomic and proteomic data from a growing number of species should soon shed light on the evolution of specific molecular components of nociceptive systems.

5.15.2.1.1 Identification of nociceptors in diverse phyla

Physiological identification and characterization of nociceptors is challenging because the somata are usually dispersed among those of many other types of neurons, and the fine peripheral and central fibers are essentially inaccessible for direct intracellular examination in living preparations. Nevertheless, nociceptors have now been demonstrated convincingly in representatives of all the major animal phyla (Figure 1), including nematode worms (Tobin, D. M. and Bargmann, C. I., 2004), leeches (Nicholls, J. G. and Baylor, D. A., 1968), insects (Tracey, W. D. Jr., *et al.*, 2003), mollusks (Illich, P. A. and Walters, E. T., 1997), and various chordates, including fish (Sneddon, L. U. *et al.*, 2003), amphibians (Lynn, B. and O'Shea, N. R., 1998), reptiles (Liang, Y. F. *et al.*, 1995), birds (Holloway, J. A. *et al.*, 1980), and mammals (Light, A. R., 1992). Additional species, including snails (Malyshev, A. Y. and Balaban, P. M.,

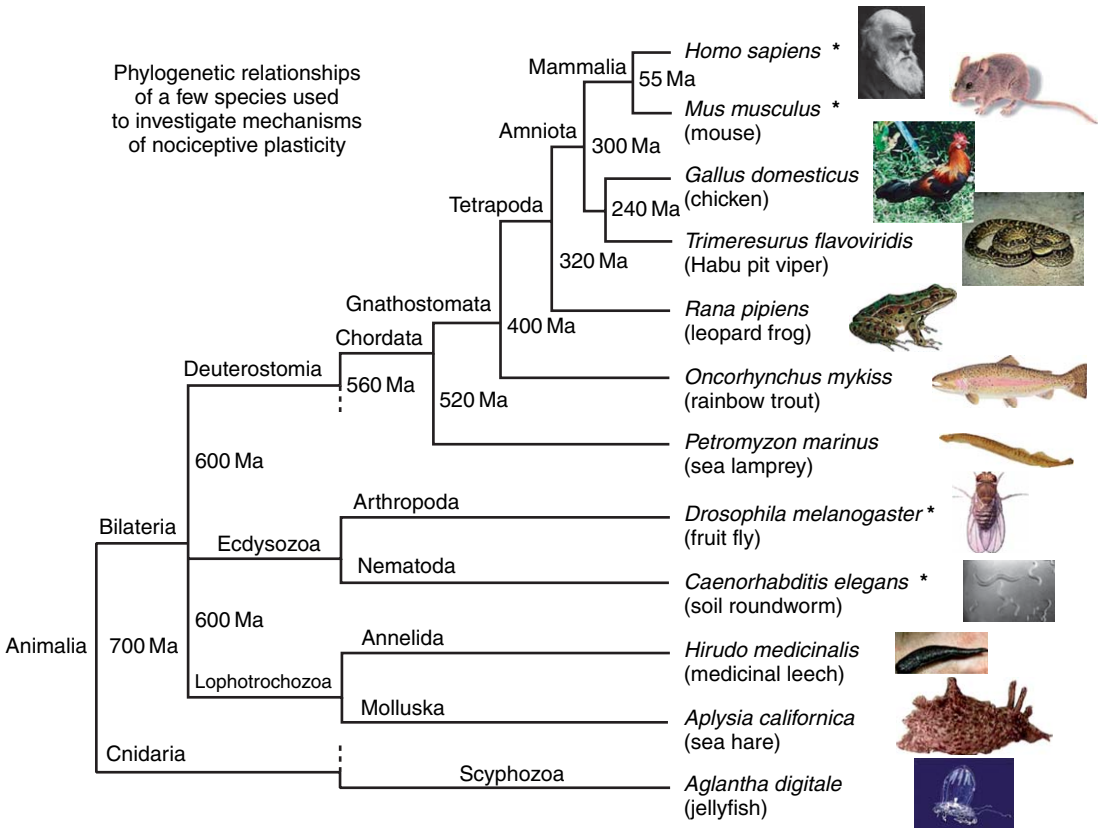

Figure 1 Greatly simplified phylogeny of a few selected species (right) that have been used to investigate nociceptive biology. Numbers indicate approximate time of divergence (millions of years ago, Ma) of the indicated groups (Dawkins, R., 2004). Groupings reflect recent molecular phylogenetics rather than traditional views based on morphological evidence. The traditional phyla indicated on this chart are chordata, arthropoda, nematoda, annelida, molluska, and cnidaria. Because of the paucity of fossil evidence prior to the Cambrian period (more than 540 Ma) and uncertainties in molecular clocks over longer periods, the older times of divergence on the chart are much rougher estimates than the more recent ones. Asterisks indicate species for which complete genome sequence information is currently available.

2002) and lampreys (Christenson, J. et al., 1988) have mechanosensory neurons that are likely to be nociceptive, despite their relatively low mechanical thresholds, because the tissue they innervate is delicate enough to be damaged by modest pressures (see Illich, P. A. and Walters, E. T., 1997).

5.15.2.1.2 Conserved mechanisms of nociceptive transduction

Tissue damage can be produced by various mechanical forces and chemical agents as well as by excessive temperature changes, so one would expect that nociceptors utilize diverse stimulus transduction mechanisms. Combined molecular and physiological analyses of nociceptive transduction have revealed important mechanisms in a few species. Many forms of mechanotransduction, perhaps including the transduction of noxious forces in some cells, depend upon depolarizing current entry through channels in the degenerin/epithelial Na^+ channel (DEG/ENaC) family. Several of these channels are required for activation of low-threshold mechanosensory neurons in the nematode, *C. elegans* (Tobin, D. M. and Bargmann, C. I., 2004), while in mice some channel subunits within this same family are acid sensitive (DRASIC/ASIC3) and contribute to the responses of some nociceptive neurons both to acid and to noxious pinch (Price, M. P. *et al.*, 2001). Another family of channels, the transient receptor potential (TRP) superfamily, has demonstrated its importance for nociceptive transduction in both vertebrates and invertebrates. TRPV channels in *C. elegans* are required for nociceptive, osmosensory, mechanosensory, and some chemosensory responses (Tobin, D. M. and Bargmann, C. I., 2004). In mammals, TRPV1 channels in sensory neurons are activated by heat, acid, capsaicin (the pungent vanilloid

ingredient of chili peppers), and other chemicals (Krause, J. E. *et al.*, 2005). Mice lacking TRPV1 channels show impaired sensory and behavioral responses to heat, vanilloids, and inflammation (Caterina, M. J. *et al.*, 2000). TRP channels also transduce noxious stimuli in the fly, *Drosophila*; mutations of the painless gene (which encodes a TRPA family member) nearly eliminate nociceptive behavioral responses of larvae to noxious heat or mechanical stimuli (Tracey, W. D., Jr., *et al.*, 2003). TRPA family channels are found in vertebrate nociceptors as well, where they are activated by noxious cold, various pungent compounds, and bradykinin (Bandell, M. *et al.*, 2004). These recent results show that nociceptive transduction in at least three different phyla makes use of shared families of ion channels, notably TRPV and TRPA channels, and perhaps DEG/ENaC channels. However, these channel families are not specific to nociception; each family also has members that are involved in innocuous mechanosensation (including hearing in *Drosophila*) and various forms of chemosensation (Tobin, D. M. and Bargmann, C. I., 2004). Thus, nociception has exploited a number of ancient and versatile ion channel families that have also been used during evolution for additional forms of sensory transduction.

5.15.2.1.3 Nociceptor-specific gene expression

Although evolution is opportunistic and tends to find multiple uses for individual gene products, some remain functionally specialized. Several genes have been found to be expressed relatively selectively in mammalian nociceptors, suggesting specialized functions related to nociceptive processing. These include the TTX-resistant, voltage-gated Na^+ channels, NaV1.8 and NaV1.9, which show alterations after nerve injury that are likely to contribute to neuropathic pain (Lai, J. *et al.*, 2004). They also include a family of receptors called Mas-related genes (MRG) (Dong, X. *et al.*, 2001) or sensory neuron-specific G-protein-coupled receptors (SNSR) (Lembo, P. M. et al., 2002). These sensory neuron receptors have displayed exceptionally rapid recent evolution in some mammals (Choi, S. S. and Lahn, B. T., 2003), and might have first appeared in the chordate lineage. Rapid changes within the MRG family are illustrated dramatically by the variation in nociceptor-specific MRG genes within a single mammalian order; mice have 22 MRGA and 14 MRGC genes, whereas gerbils, and rats only have one of each (Zylka, M. J. *et al.*, 2003). Only six of the 13 MRG genes in humans are clearly orthologous (displaying sequence homology across species) with mice MRG genes. Little is known about the functions of these receptors, although the diversity of ligands implicated for them include a variety of RFamide peptides thought to be antinociceptive (Dong, X. *et al.*, 2001 and see below). The recency and rapidity of change in the MRG family suggests that strong selection pressures may be acting on antinociceptive modulation of nociceptors in vertebrates, including primates (Choi, S. S. and Lahn, B. T., 2003; Zylka, M. J. *et al.*, 2003; Zhang, L. *et al.*, 2005). Further investigation of the distribution – across diverse taxa – of genes found to be preferentially expressed in mammalian nociceptors should provide interesting insights into the evolution of nociceptive systems.

5.15.2.2 Nociceptive Networks and Antinociceptive Modulation

The capability for rapid detection of noxious stimuli could only have been selected during evolution if systems to translate this information into adaptive behavior had also been selected. Almost every animal that has been examined, from jellyfish to humans, displays withdrawal and/or escape responses to noxious stimulation (Walters, E. T., 1994), although these responses are inhibited under some circumstances (see further ahead).

5.15.2.2.1 Common nociceptive functions mediated by diverse neural circuits

Nociceptive responses are mediated by neural circuits that range enormously in complexity across different animals. In cnidarians (hydra, jellyfish, sea anemones), some simple withdrawal reflexes may be mediated in part by just a two-cell pathway involving a multifunction sensory-motor neuron synaptically connected to epithelial-muscular cells. However, even in cnidarians, which lack a brain or central ganglia, relatively complex withdrawal and escape responses can be mediated by a neural net containing sensory, motor, and interneurons (e.g., Mackie, G. O., 2004). At the other end of the behavioral spectrum, nociceptive circuits in mammals involve not only diverse types of sensory, motor, and interneurons at the spinal level, but vast numbers of neurons in higher brain structures (e.g., Craig, A. D., 2003). Different populations of neurons process nociceptive sensory information, generate defensive motor patterns, and modulate nociceptive responses depending upon the state of the organism and its previous experience. These basic nociceptive/defensive tasks

are also mediated by functionally similar, but much simpler, neural circuits in several invertebrate species that have been investigated, including *C. elegans* (Wittenburg, N. and Baumeister, R., 1999), the medicinal leech (Shaw, B. K. and Kristan, W. B., Jr. , 1995), and several gastropod mollusks – *Aplysia* (Cleary, L. J. et al., 1995), *Tritonia* (Getting, P. A., 1977), and *Helix* (Balaban, P. M., 2002). Although the organization of these circuits differs greatly among the mammalian and invertebrate species examined, common mechanisms of nociceptive plasticity appear to be shared by these diverse animals (see further ahead).

5.15.2.2.2 Widespread occurrence of antinociceptive mechanisms

One of the most important functions of nociceptive circuits is to modulate nociceptive responses, so that the threshold, selection, and intensity of defensive responses are well matched to the nature and context of a noxious threat. The form of modulation that has received the most experimental attention in nociceptive systems is antinociception, which produces analgesia or hypoalgesia in humans. Many authors have argued that it is adaptive for an animal to inhibit responses, including pain and recuperative responses evoked by injury, during active defense in life-threatening encounters with predators or aggressive conspecifics (see Walters, E. T., 1994). Indeed, most animals examined thus far, including various invertebrates, transiently suppress appetitive, recuperative, and other nondefensive behaviors that might compete with urgent fight-or-flight responses evoked immediately by noxious stimuli. In mammals (Light, A. R., 1992) and at least one invertebrate, *Aplysia* (Cleary, L. J. *et al.*, 1995), inhibitory effects of noxious stimulation are exerted at multiple stages within sensory-motor pathways. Strong pre- and/or postsynaptic inhibition during noxious stimulation occurs at the first synapse in these pathways (from somatic primary afferent neurons) in various species, including mammals (Light, A. R., 1992) and *Aplysia* (Mackey, S. L. *et al.*, 1987).

5.15.2.2.3 Recent evolution of opiate systems

There has been much interest in the phylogenetic distribution of antinociceptive neuropeptides, and especially the opioid family because of its well-known analgesic functions in humans. Pharmacological, immunocytochemical, and biochemical studies have suggested that opiate-like substances and opiate receptors occur in nervous and immune systems of diverse species, including invertebrates and even unicellular organisms (Stefano, G. B. *et al.*, 2003). However, genes within the opioid/orphanin family have not been detected in the genomes of *C. elegans* or *Drosophila* (nor have genes within the corresponding melanocortin receptor family), which supports the hypothesis that this gene family first appeared in a deuterostome ancestor around the time that the chordate lineage diverged (Dores, R. M. *et al.*, 2002) (Figure 1). The only invertebrate opioids that have been sequenced are proteins related to pro-opiomelanocortin (POMC), which have been found in immunocytes in a leech (Salzet, M. *et al.*, 1997) and in the mussel, *Mytilus edulis* (Stefano, G. B. *et al.*, 1999). Paradoxical features of these POMC sequences led to the suggestion that the vertebrate-like POMC in these invertebrates may have come somehow by cross-phylum gene transfer (Dores, R. M. *et al.*, 2002), and these unusual features reinforce indications that antinociceptive opioids may be a chordate innovation. In contrast, another neuropeptide family having antinociceptive functions is widespread in the animal kingdom: the RFamide family which is expressed in many phyla, including cnidarians, nematodes, arthropods, mollusks, and chordates (Li, C. *et al.*, 1999; Nichols, R., 2003). In mammals some RFamides activate MRG receptors (Dong, X. *et al.*, 2001) (and see above), while in *Aplysia* FMRFamide can produce both short-term and long-term inhibition of synaptic transmission from nociceptive sensory neurons (Montarolo, P. G. *et al.*, 1988). However, RFamides also have pronociceptive actions (Yudin, Y. K. *et al.*, 2004) as well as many actions unrelated to nociceptive modulation.

5.15.2.3 Nociceptive Plasticity and Sensitization

As just discussed, many animals show a transient reduction in responsiveness to somatic stimuli during active defensive behavior. However, if an animal is injured and escapes, it often displays enhanced responsiveness to somatosensory stimuli while it recuperates. This nociceptive sensitization (and hyperalgesia in some species) is targeted to the injured region and can be very long lasting. It facilitates defensive responses, helping to protect an injured animal during a period when it may be weakened and emitting wound-related signals that can attract the attention of predators, parasites, and aggressive competitors (Walters, E. T., 1994). The persistence of nociceptive sensitization during recuperation periods that can last weeks or longer raises

the possibility that nociceptive sensitization may utilize mechanisms that are shared with other long-lasting neural alterations, such as learning and memory. Demonstrations that the same plasticity mechanisms contribute both to nociceptive sensitization and to learning and memory, and evidence that these mechanisms have common functions in very distantly related animal species, indicate that evolutionary links between injury and memory may be quite primitive (Walters, E. T., 1994; Weragoda, R. M. *et al.*, 2004). Of several apparent commonalities between injury-induced and learning-related mechanisms in diverse phyla, three will be considered here.

5.15.2.3.1 *N*-Methyl-D-asparate-receptor-dependent long-term synaptic potentiation

As in mammals (Ji, R. R. *et al.*, 2003), somatosensory afferents in several intensively studied invertebrate species appear to release glutamate, which acts upon both NMDA and non-NMDA postsynaptic receptors. These invertebrates include *C. elegans* (Brockie, P. J. *et al.*, 2001), *Aplysia* (Dale, N. and Kandel, E. R., 1993), *Helix* (another snail) (Bravarenko, N. I. *et al.*, 2003), and the leech (Burrell, B. D. and Sahley, C. L., 2004). In mammals (Ji, R. R. *et al.*, 2003), *Aplysia* (Lin, X. Y. and Glanzman, D. L., 1994), *Helix* (Nikitin, V. P. *et al.*, 2002), and the leech (Burrell, B. D. and Sahley, C. L., 2004), intense activation of a sensory pathway (which under normal conditions would occur during noxious stimulation of the periphery) strongly depolarizes second-order neurons and activates NMDA receptors, leading to LTP in the nociceptive pathway, which contributes to nociceptive sensitization. As in mammals (Martin, S. J. *et al.*, 2000), in *Aplysia* (Murphy, G. G. and Glanzman, D. L., 1997), *Helix* (Nikitin, V. P. *et al.*, 2002), and the leech (Burrell, B. D. and Sahley, C. L., 2004), NMDA-receptor-dependent LTP has been implicated as a mechanism of learning and memory.

5.15.2.3.2 Activation of the transcription factor, Ca^{2+} and cAMP Response Element-Binding Protein

A second commonality is a role for a transcription factor, the Ca^{2+} and cAMP response element-binding protein (CREB), in inducing long-term neuronal alterations that require changes in gene transcription and protein synthesis. A key role for this transcription factor was first implicated in long-term memory formation in *Aplysia*, *Drosophila*, mice, and rats (Silva, A. J. *et al.*, 1998; Kandel, E. R., 2001). Later, hyperalgesia was found to be accompanied by CREB phosphorylation in the rat spinal cord (Ji, R. R. and Rupp, F., 1997), and interference with CREB binding to DNA was shown to attenuate sensitized behavioral responses in a rat neuropathic pain model (Ma, W. et al., 2003). Interestingly, the sensory neurons from *Aplysia* originally used to demonstrate possible roles of CREB in long-term memory formation (Kandel, E. R., 2001) are nociceptive and exhibit long-term hyperexcitability following noxious cutaneous stimulation, and this hyperexcitability is blocked by injection of CRE oligonucleotides to prevent CREB binding (Lewin, M. R. and Walters, E. T., 1999). Cellular signals involved in activating CREB are also common to both memory and nociceptive sensitization/hyperalgesia in various phyla. Particular attention has been paid to the roles of PKA and MAPK (ERK) in CREB-related plasticity in mammalian hippocampus and forebrain (Waltereit, R. and Weller, M., 2003), mammalian spinal cord (Kawasaki, Y. *et al.*, 2004), and *Aplysia* sensory neurons (Kandel, E. R., 2001).

5.15.2.3.3 Local protein synthesis and primitive memory mechanisms

The observations mentioned above suggest that evolution made use of common basic mechanisms, including NMDA-receptor-dependent LTP and CREB-dependent transcriptional regulation, to induce long-lasting neuronal alterations underlying quite different functions: nociceptive sensitization and learning. Because strong selection pressures would have favored adaptive responses to peripheral injury at the earliest stages of animal evolution (prior to the evolution of brains complex enough for associative learning), it has been suggested that adaptive responses to peripheral injury, including nociceptive sensitization, emerged first as an adaptation to tissue damage and later evolved into mechanisms of learning and memory (Walters, E. T., 1994). In ancient, soft-bodied animals that were ancestral to most contemporary animals (Figure 1), some of these mechanisms may have functioned initially at sites of peripheral injury in axons and terminals. A vestige of early memory-like mechanisms linked to peripheral injury might be represented today by localized, long-term hyperexcitability of peripheral axon segments of nociceptive sensory neurons found in *Aplysia* (Weragoda, R. M. *et al.*, 2004). This sensitizing axonal alteration is induced by nerve crush or local depolarization and, like the late phase of LTP in mammalian

hippocampus (Tang, S. J. *et al.*, 2002), it requires local, rapamycin-sensitive protein synthesis (Weragoda, R. M. *et al.*, 2004). It has not yet been determined whether this apparently primitive mechanism contributes to neuropathic pain in mammals, but evidence for intra-axonal protein synthesis following peripheral nerve injury has been found in axons of mammalian DRG neurons (e.g. Zheng, J. Q. *et al.*, 2001).

5.15.3 Evolution of Emotional Components of Pain

Perhaps the most commonly asked question related to the evolution of pain is one that has yet to be answered by scientists: Which animals feel pain? This question is critical for animal welfare issues, and is also of considerable philosophical interest (Allen, C., 2004). Many philosophers of science have argued that a human observer cannot know for sure whether another being or species has subjective, conscious experiences such as pain. The existence of emotional pain in other species may defy proof, but evolutionary and neurobiological considerations indicate strongly that these components of pain did not emerge *de novo* in humans, while also suggesting that the capacity to experience subjective pain is not a universal animal trait.

5.15.3.1 Emotional Awareness is not Required for Nociceptive Responses

As discussed above, most animals have nociceptive systems that detect noxious stimuli and activate defensive responses. Nociceptive reflexes and even nociceptive plasticity, however, can almost certainly operate without conscious, emotional experience because these responses are expressed not only in the simplest animals but also in greatly simplified physiological preparations, such as a spinalized rat or an *Aplysia* ganglion connected to part of the animal's tail. Moreover, in human patients nociceptive reflexes can be expressed without conscious awareness below the level of a spinal transection.

5.15.3.2 Even Snails Display Complex Motivational Effects after Noxious Stimulation

In addition to the abilities to detect noxious stimuli and activate defensive responses, adaptations to actual or incipient tissue damage include motivational responses, and these too can be observed throughout the animal kingdom. Pain motivates humans and other mammals to avoid contexts or actions associated with the onset of the pain, and similar motivational effects of noxious stimulation (often electric shock that activates nociceptors) have been used experimentally to produce aversive learning in a wide variety of invertebrates, including flies, worms, and snails (reviewed by Krasne, F. B. and Glanzman, D. L., 1995; Waddell, S. and Quinn, W. G., 2001; Rankin, C. H., 2004). Some of these motivational effects appear remarkably similar to those produced by noxious stimuli in mammals. For example, pairing an odor with strong cutaneous shock causes the previously neutral odor to evoke a conditioned fear-like state in *Aplysia*, so that the odor comes to evoke a freezing response, inhibit appetitive responses, and facilitate defensive responses to tactile stimuli (Walters, E. T. *et al.*, 1981).

5.15.3.3 Cognitive and Emotional Responses to Noxious Stimulation Differ across Species

Although relatively simple invertebrates show functional similarities to vertebrates (sometimes with conserved molecular mechanisms) in detecting noxious stimuli, activating defensive behavior, and motivating learned and unlearned responses to a noxious event, vast differences in the size and structure of their brains indicate that major differences exist between most invertebrates and many vertebrates in the cognitive and possible emotional processing of information about tissue damage. For example, in *Aplysia*, the body surface is represented by a somatotopic map formed by nociceptor somata in central ganglia (Walters, E. T. *et al.*, 2004), and peripheral injury causes nociceptor soma hyperexcitability selectively in nociceptors representing the injured region. These and other sensory changes are sufficient to alter reflexive responses to stimuli received by the injured region, but they do not cause these normally silent sensory neurons to become spontaneously active. If one assumes that ongoing pain requires ongoing neural activity somewhere in a nervous system, then an absence of ongoing activity may be taken as evidence that tissue damage fails to produce long-lasting, pain-like states. In relatively simple invertebrates, one can systematically sample the activity of individual neurons and use optical imaging methods to sample the activity of populations of neurons to test this possibility following strong noxious stimulation. Although

many more neurons need to be sampled before firm conclusions can be made, preliminary observations in *Aplysia* suggest that a persistent (lasting days or longer) increase in ongoing neural activity within the CNS does not accompany long-term, nociceptive sensitization of defensive reflexes. Instead, sensitization lasting days or weeks appears to be maintained largely by synaptic facilitation and hyperexcitability of sensory neurons, which remain silent in the absence of peripheral stimulation. An apparent lack of ongoing activity in the *Aplysia* CNS would contrast with increases in neural activity that probably occur in some regions of the human brain during persistent pain states (Casey, K. L., 2000).

Investigating the evolution of emotional aspects of pain is an enormous challenge because the biological functions of conscious pain (as opposed to unconscious nociceptive responses) are not obvious and the neural substrates are very difficult to define. Nevertheless, there are many intriguing observations in these areas. For example, much research has been stimulated by the suggestion that conscious awareness of an animal's own bodily states might help it predict the behavioral states (read the mind) of other animals (Keenan, J. *et al.*, 2003). Conscious awareness of bodily states, including the emotional awareness of pain, involves dynamic neural representations of the body (e.g. Craig, A. D., 2003). Even the most complex brains of invertebrates, such as the octopus or honeybee, as well as the brains of non-mammalian vertebrates, have much smaller numbers of neurons and less obviously organized brain structures than found in behaviorally sophisticated mammals such as primates and cetaceans, and thus presumably less capacity for such representations. Indeed, extremely complex neuroanatomical substrates support the multiple representations and meta-representations of the body that are associated with emotional awareness and suffering in humans, which has suggested to some that these aspects of pain may not occur in animals lacking, for example, an equivalent to the anterior insular cortex of primates (Craig, A. D., 2003). Although direct measurement of subjective pain in animals is not possible, clues about the evolution of this capacity may still come from comparing across a broad range of species possible functions of emotional awareness as well as the neural substrates critical for expressing signs of such awareness.

5.15.4 Conclusions

Nociceptive mechanisms that permit an animal to detect, respond to, and remember peripheral injury are found throughout the animal kingdom. Some of these are likely to represent convergent (analogous) evolutionary responses to similar injury-related selection pressures in diverse organisms, which may depend upon different molecular substrates in different animal groups. For example, while most animals show transient, antinociceptive responses to noxious stimulation, the use of opiates and melanocortin receptors for antinociception may largely be restricted to vertebrates. On the other hand, emerging molecular genetic information indicates that other nociceptive mechanisms have been highly conserved from mechanisms that must have already been present around 600 million years ago in worm-like animals that were the last common ancestors of modern roundworms, flies, leeches, snails, mice, and humans (Figure 1). Conserved (homologous) nociceptive mechanisms that have been revealed thus far are related to nociceptive transduction (e.g., TRP channels), plasticity of nociceptor synapses (e.g., NMDA-receptor-dependent LTP), and regulation of gene transcription in nociceptive pathways (e.g., CREB activation). Because of dramatic increases in molecular genetic information from all the major phyla and the coupling of this information with continuing physiological studies of various species, it seems likely that knowledge gained from investigating highly conserved mechanisms in disparate creatures will provide insights that might help control intransigent pain states in humans. Comparative studies may also shed some light on the selection pressures that shaped the evolution of emotional aspects of pain, even though the subjective experience of pain may not be amenable to direct experimental investigation in other species.

Glossary

allele One possible form (or variant) of a gene, defined by its particular nucleotide sequence.

genotype The inherited alleles (one from each parent) at a genetic locus (e.g., a gene).

phenotype An observable or measurable biological trait.

pleiotropy The involvement of a single gene in more than one phenotype

polymorphism see Allele.

5.16.1 Finding Genes Associated with Phenotypic Variability

With recent developments in classical and molecular genetic techniques, identifying genes, and the DNA sequence variants in or near them, responsible for disease susceptibility and normal variation in biological phenotypes is becoming increasingly tractable. Two main methodologies are employed to this end: genetic linkage mapping and genetic association studies (see Lander, E. S. and Schork, N. J., 1994). These approaches have begun to be applied to the study of pain (see Mogil, J. S., 2004). For example, variable sensitivity of humans to experimental and clinical pain has been provisionally associated with the genes *COMT* (catechol-*O*-methyltransferase) (Zubieta, J. K. *et al.*, 2003; Diatchenko, L. *et al.*, 2005), *OPRD* (δ-opioid receptor; Kim, H. *et al.*, 2004), *TRPV1* (transient receptor potential vanilloid type 1; Kim, H. *et al.*, 2004), *OPRM* (μ-opioid receptor gene) (Klepstad, P. *et al.*, 2004; Fillingim, R. B. *et al.*, 2005), *IL6* (interleukin-6; Noponen-Hietala, N. *et al.*, 2005), *IL1* (interleukin-1; Solovieva, S. *et al.*, 2004), and others. These association studies were inspired in some cases by a mouse linkage mapping finding, in others by the phenotype of a null mutant (transgenic knockout) mouse, and in others simply by the known involvement of the protein in pain processing.

There are a finite number of human genes, current estimates are less than 30 000, but a virtually unlimited number of biological phenotypes. It is thus necessarily true that every gene will eventually be shown to be genetically associated with multiple (and possibly unrelated) traits. This principle is known as pleiotropy. Currently, one of the best-known examples of a gene with pleiotropic effects is *MC1R*, the gene coding for the melanocortin-1 receptor (MC1R).

5.16.2 MC1R and the Melanocortin-1 Receptor

The melanocortin receptor family consists of five subtypes, MC1R–MC5R. These receptors bind the melanocortin peptides, including α-melanocyte-stimulating hormone (α-MSH), β-MSH, γ-MSH, and adrenocorticotrophic hormone (ACTH), all cleaved from the proopiomelanocortin (*POMC*) gene along with β-endorphin (see Tatro, J. B., 1996; Wikberg, J. E. S., 1999; Abdel-Malek, Z. A., 2001; Starowicz, K. and Przewlocka, B., 2003). The

receptors are transcribed from five separate genes, and each receptor has differential tissue distributions and affinities for the melanocortins. All melanocortin receptor subtypes couple positively to adenylate cyclase when activated (Chhajlani, V. and Wikberg, J. E. S., 1992). The MC1R, previously known as the α-MSH receptor, actually has equal affinity for ACTH, and is found primarily in melanocytes of the skin. It is also been demonstrated in a variety of glial cells, the testes, placenta, pituitary (see Tatro, J. B., 1996; Wikberg, J. E. S., 1999; Abdel-Malek, Z. A., 2001; Starowicz, K. and Przewlocka, B., 2003), and in neurons of the midbrain periaqueductal gray (Xia, Y. *et al.*, 1995). The role of α-MSH acting on melanocyte MC1Rs to regulate pigmentation of skin and hair by stimulation of eumelanin synthesis has been understood in great detail for some time (see Eberle, A. N., 1988). Other α-MSH effects are also well known, and have been attributed to actions at the MC1R. For example, α-MSH has potent anti-inflammatory and antipyretic activity (see Tatro, J. B., 1996), and may play a role in nerve regeneration (see Starowicz, K. and Przewlocka, B., 2003) and female sexual behavior (Pfaus, J. G. *et al.*, 2004). Injection of α-MSH (or ACTH) into the brain has been reported to affect nociceptive sensitivity (see Starowicz, K. and Przewlocka, B., 2003), usually in a manner opposed to the actions of endogenous opioids, although the literature is contradictory. It is possible that some or all of these effects are mediated at spinal MC4Rs, since the MC4R-selective antagonist, SHU9119, reduces neuropathic hypersensitivity states when injected into the spinal cord (Vrinten, D. H. *et al.*, 2001).

Given the known role of MC1Rs in pigmentation and the highly polymorphic nature of *MC1R*, the hypothesis that the *MC1R* gene might be associated with variability in human hair color and skin tone was palpable. Indeed, Valverde P. *et al.* (1995) demonstrated that the inheritance of loss-of-function *MC1R* alleles was genetically associated with red hair and fair skin in humans. Subsequent work has determined that approximately 60–85% of natural redheads are so because of their inheritance of variant alleles of *MC1R*, especially those producing the very common Arg151Cys, Arg160Trp, and Asp294His amino acid substitutions (see Schaffer, J. V. and Bolognia, J. L., 2001). Red hair is much more likely if multiple alleles are inherited, and the number of variant alleles is important in determining the precise shade of red. In addition, it has been subsequently demonstrated that *MC1R* is the major gene responsible for solar lentigines (i.e., freckles; Bastiaens, M. *et al.*, 2001a), reduced tanning ability (Healy, E. *et al.*, 2000), and skin cancer (malignant melanoma, squamous cell, and basal cell carcinoma) susceptibility even in individuals without red hair (Palmer, J. S. *et al.*, 2000; Bastiaens, M. *et al.*, 2001b). It should be noted that *MC1R* genetics is rather complex, with a large number of known rare (<1% allele frequency) mutations and at least three common variants (Val60Leu, Val92Met, and Arg163Gln) that are only partially penetrant or completely silent, producing no impairment of MC1R functioning (see Schaffer, J. V. and Bolognia, J. L., 2001).

5.16.3 MC1R and Analgesia

Using genetic linkage (formally, quantitative trait locus or QTL) mapping, a gene affecting the magnitude of swim stress-induced analgesia (SIA) in female but not male mice was localized to distal mouse chromosome 8 (Mogil, J. S. *et al.*, 1997). This SIA was previously demonstrated to be sex-specific in its neurochemical mediation (e.g., Mogil, J. S. *et al.*, 1993; Kavaliers, M. and Galea, L. A. M., 1995). Specifically, pharmacological blockade of the *N*-methyl-D-aspartate (NMDA) excitatory amino acid receptor abolishes SIA in male rodents, but does not do so (at any dose or in any estrous phase) in females. Kavaliers M. and Choleris E. (1997) found that analgesia from a κ-opioid-selective agonist, NPC12626, was similarly sexually dimorphic in its neurochemical mediation, being blocked by NMDA antagonists only in males. The possible sex-specificity of κ-opioid analgesia was then a hot topic, as data from Gear R. W. *et al.* (1996) suggested that κ-opioid-acting drugs may only produce efficacious analgesia, in the third molar extraction model, in women. Mogil J. S. *et al.* (2003) hypothesized that if SIA and κ-opioid analgesia were both sexually dimorphic, and a female-specific linkage on chromosome 8 had been already demonstrated for SIA, one would likely be seen for κ-opioid analgesia as well. This was quickly confirmed using the κ-opioid-selective compound, U50,488 (Mogil, J. S. *et al.*, 2003), but the confidence interval containing the gene(s) responsible for the linkage was quite large. Of the ~200 murine genes in this region, however, one emerged as a high-probability candidate: *Mc1r*. Evidence for its candidacy included the possible role of α-MSH and/or ACTH as antiopioid peptides (see above) and the demonstration of neuronal MC1Rs in the periaqueductal gray (Xia, Y. *et al.*, 1995),

a supraspinal region of well-known importance in pain modulation (see Basbaum, A. I. and Fields, H. L., 1984). It should also be noted that dynorphin can bind with reasonable affinity in *in vitro* assays to MC1R (Quillan, J. M. and Sadee, W., 1997).

Using a three-pronged strategy, Mogil J. S. and colleagues have provided considerable supporting evidence that the mouse *Mc1r* gene is indeed the female-specific QTL for U50,488 analgesia. First, null mutant recessive yellow (C57BL/6-*Mc1r*$^{e/e}$, or *e/e*) mice, which arose spontaneously rather than being engineered using transgenic technology (see Cone, R. D. *et al.*, 1996), were tested for U50,488 analgesia along with their C57BL/6 wild-type controls. We found that female but not male *e/e* mutants displayed significantly greater U50,488 analgesia (see Figure 1(a)),

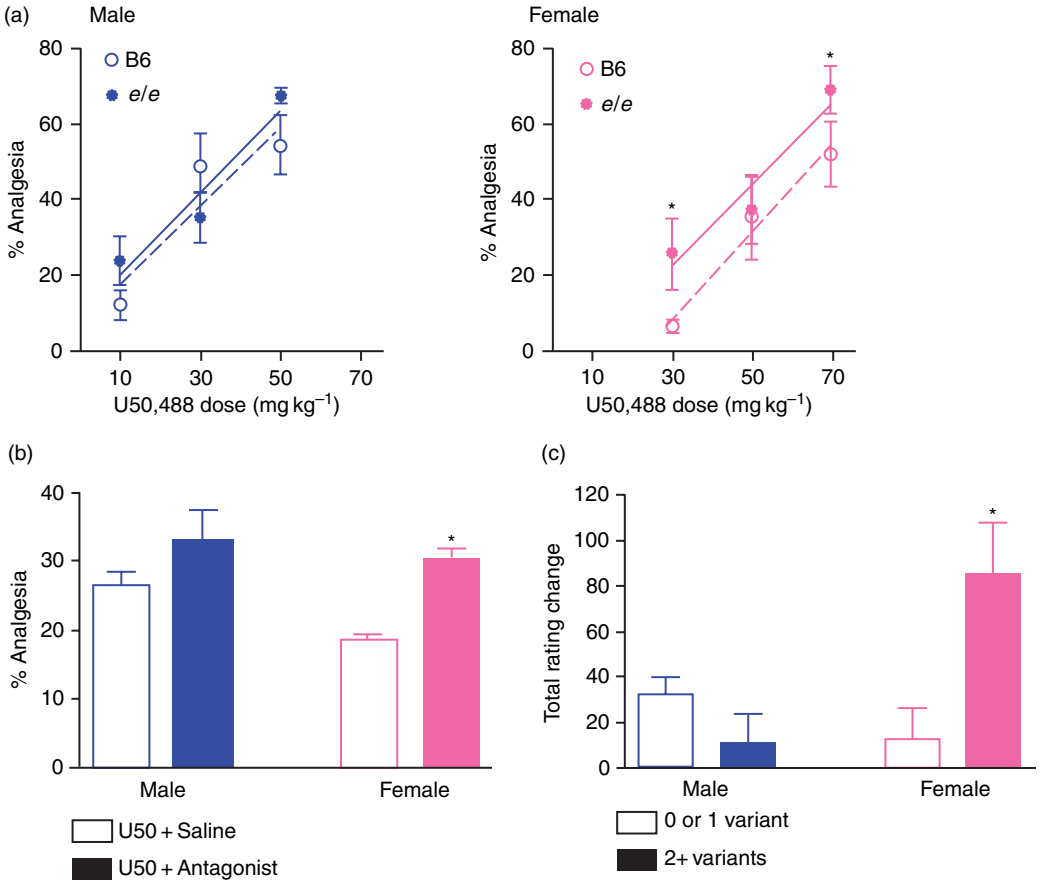

Figure 1 Female-specific effect of MC1R functional status on κ-opioid analgesia in mice and humans. (a) Response on the 49 °C tail-withdrawal test to systemic injection of various doses (10–70 mg kg^{-1}, subcutaneous (s.c.)) of the selective κ-opioid agonist, U50,488, in male and female spontaneous mutant recessive yellow (*e/e*) mice and their wild-type counterparts, C57BL/6 (B6). The *e/e* mutants of both sexes have nonfunctional MC1Rs due to a frameshift mutation at position 183. Symbols represent mean ± standard error of the mean (SEM) percent of total analgesia (based on area under the time–effect curve) over a 60 min testing period postdrug administration. (b) Female-specific potentiation of U50,488 (U50) analgesia (70 mg kg^{-1}, s.c.), on the 49 °C tail-withdrawal test, by injection of a peptidergic MC1R antagonist, Ac-Nle-Asp-Trp-DPhe-Nle-Trp-Lys-NH_2 (20 μg/mouse in 2.5 μl), into the lateral ventricles of outbred mice. Bars represent mean ± SEM percent of total analgesia (based on area under the time–effect curve) over a 60-min testing period postdrug administration. (c) Female-specific influence of *MC1R* genotype on pentazocine (0.5 mg kg^{-1}, intravenous) analgesia in humans. Subjects of both sexes were studied in two experimental sessions as described in detail in Mogil J. S. *et al.* (2003). Bars represent mean ± SEM difference scores for summed pain intensity ratings (0–100; 5 ×) during the ischemic pain procedure, computed by subtracting postdrug from predrug ratings, in subjects with consensus sequence or one *MC1R* variant (0 or 1 variant) and subjects with two or more *MC1R* variants (2+ variants). The 2+ variant subjects possessed nonfunctional MC1Rs, and were unanimously redheaded. *$P < 0.05$ compared to other condition within-sex. Adapted from Mogil, J. S. *et al.* 2003. The melanocortin-1 receptor gene mediates female-specific mechanisms of analgesia in mice and humans. Proc. Natl. Acad. Sci. U. S. A. 100, 4867–4872.

and perhaps more importantly, that this analgesia was sensitive to NMDA blockade in the female mutants, suggesting that they had switched over to the malelike system (Mogil, J. S. *et al.*, 2003). This switching has been observed before and since with other hormonal disruptions of the female system (Mogil, J. S. *et al.*, 1993; Kavaliers, M. and Galea, L. A. M., 1995; Sternberg, W. F. *et al.*, 2004). Second, injection of a selective peptidergic MC1R antagonist, Ac-Nle-Asp-Trp-DPhe-Nle-Trp-Lys-NH_2, into the cerebral ventricles of (outbred) male and female mice produced a potentiation of U50,488 analgesia only in females (see Figure 1(b)), and furthermore rendered that analgesia newly sensitive to inhibition by an NMDA antagonist (Mogil, J. S. *et al.*, 2003). Finally, Austin and Mogil have demonstrated sex and strain differences in periaqueductal gray expression of the *Mc1r* gene using quantitative polymerase chain reaction (J. S. Austin and J. S. Mogil, unpublished data) in directions entirely consistent with the hypothesis that lower MC1R functionality is associated with higher κ-opioid analgesia.

These data, supportive of the sex-specific involvement of *Mc1r* in κ-opioid analgesia in the mouse, inspired a small association study in humans designed to test the same hypothesis in our species. College-age subjects were tested for thermal and ischemic pain before and after administration of pentazocine (Talwin®; 0.5 mg kg^{-1}) or saline, and then genotyped at the human *MC1R* gene by direct sequencing of exons containing common variants. We found that pentazocine analgesia was modest in all male subjects, and also in women with functional MC1Rs (i.e., those with the consensus DNA sequence or only one variant). Women with nonfunctional MC1Rs (i.e., those with two or more variants; all phenotypic redheads) displayed robust pentazocine analgesia (Mogil, J. S. *et al.*, 2003; see Figure 1(c)).

These data represent the first time a genetic finding in the mouse has ever been directly translated to humans within a single published study. More importantly, though, the data are the first to suggest that, like the mouse, humans possess qualitatively (i.e., neurochemically) distinct mechanisms of pain modulation, since the functional status of the MC1R affected analgesic output in one sex but not the other. A follow-up study was performed, in order to determine whether *Mc1r* and *MC1R* play a role in μ-opioid analgesia in mice and humans, respectively. μ-Opioid analgesia is of much greater clinical relevance than κ-opioid analgesia due to the high μ-selectivity of most clinically used opiate drugs. In addition to differences in pain sensitivity *per se* (see Section 5.16.5 below), we found that *e/e* mice were significantly more sensitive to analgesia from both morphine and its bioactive metabolite, morphine-6β-glucuronide (Mogil, J. S. *et al.*, 2005a). Curiously, the effect of MC1R functional status on μ-opioid analgesia did not appear to be sex-specific, with both male and female mutants showing increased sensitivity (see Figure 2(b)). Again, data collected in humans were entirely analogous, with redheads of both sexes showing robustly higher morphine-6β-glucuronide inhibition of noxious electrical stimuli (Mogil, J. S. *et al.*, 2005a; see Figure 2(d)).

5.16.4 MC1R and Anesthesia

It has long been clinical lore among anesthesiologists that redheads are harder to anesthetize with inhalant anesthetics than others, but these anecdotal impressions were never tested experimentally until recently. Liem E. B. *et al.* (2004) recruited 20 young adult women (10 with red hair, 10 with dark hair), and studied the minimum alveolar concentration of desflurane required to prevent movement in response to intradermal electrical stimulation of the anterior thigh. They found that red-haired women required almost 20% more anesthetic to abolish responding. This finding regarding anesthetic sensitivity cannot easily be reconciled with the aforementioned findings regarding analgesia. If the greater response of *MC1R* mutants (i.e., redheads) to κ- and μ-opioid analgesics is reflective of higher endogenous activity of a tonically active analgesic system, one might have expected red-haired women to require less anesthetic, not more. Unfortunately, only women were tested in the study by Liem E. B. *et al.* (2004), so sex differences could not be evaluated. In apparent support of this finding, this same group tested *e/e* mutants for sensitivity to four inhaled anesthetic compounds (isoflurane, sevoflurane, desflurane, and halothane), and found that although mutant mice were not significantly less sensitive to any one anesthetic compared to controls, when data from all anesthetics were combined the genotypic difference achieved statistical significance ($P = 0.023$; Xing, Y. *et al.*, 2004).

5.16.5 MC1R and Pain

One limitation of the study by Liem E. B. *et al.* (2004) is that no attempt was made to study nociceptive sensitivity of the subjects in the absence of anesthetic,

so it was impossible to tell whether the differences observed involved differential sensitivity among genotypes to the anesthetic, or differential sensitivity to the noxious stimulus itself. It has recently been demonstrated in mice that the latter can easily be confused for the former (Mogil, J. S. *et al.*, 2005b). In a recently published follow-up study by their group (Liem, E. B. *et al.*, 2005), women (30 with red hair, 30 with dark hair) were tested for sensory thresholds, pain thresholds, and pain tolerance to electrical and thermal stimulation. No differences were seen in sensitivity to electrical stimulation, but heat and cold pain perception was higher in redheads. Redheads were also found to be resistant to subcutaneous (but not liposomal) lidocaine anesthesia against electrical stimulation (Liem, E. B. *et al.*, 2005).

These data are in contrast with an earlier study, showing no *MC1R* genotypic differences in thermal pain sensitivity (Mogil, J. S. *et al.*, 2003), although that study was probably too lightly powered to assess the issue. However, the data of Liem E. B. *et al.* (2005) are also entirely contradictory with a larger follow-up study (Mogil, J. S. *et al.*, 2005a), which observed in *e/e* mutant mice of both sexes (across a broad range of noxious stimulus modalities) and humans of both sexes a decreased sensitivity to noxious electrical stimulation (see Figures 2(a) and 2(b)). There are a number of possible reasons for the discrepancy. Methodological differences can be found between the three experiments, of course. It is difficult to blind experimenters to hair color, and it is possible that this lack of blinding was a greater issue in one

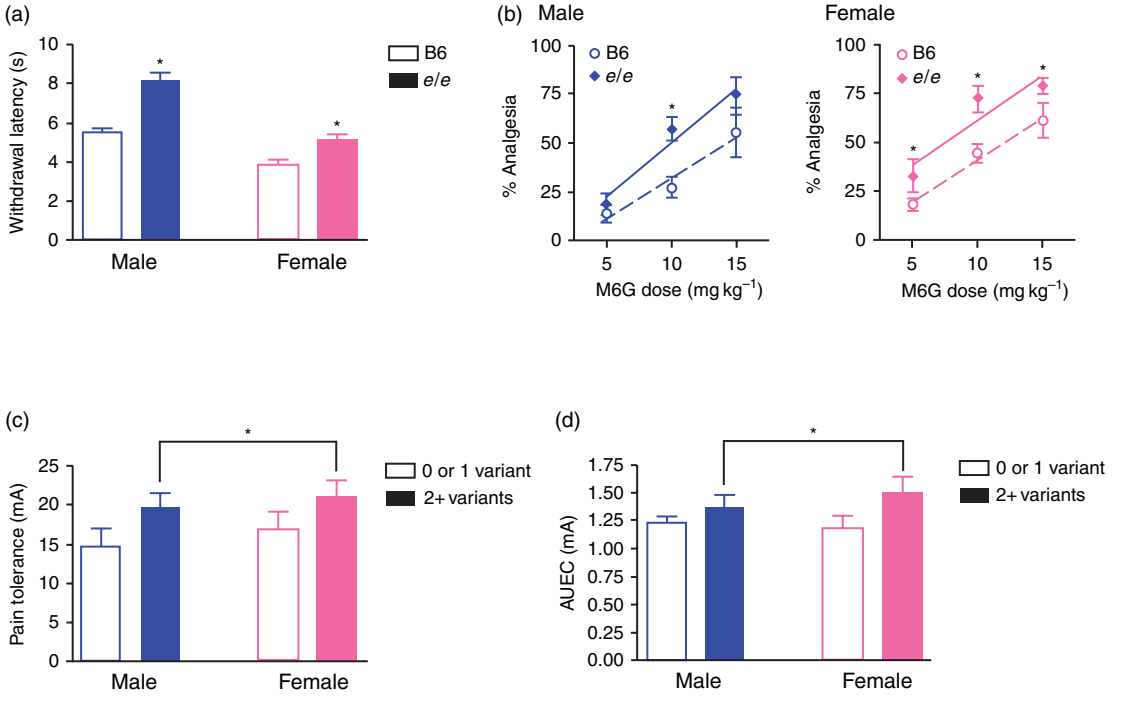

Figure 2 Effect of MC1R functional status on pain sensitivity and μ-opioid analgesia in mice and humans of both sexes. (a) Sensitivity of male and female spontaneous mutant recessive yellow (*e/e*) mice and their wildtype counterparts, C57BL/6 (B6), on the thermal paw-withdrawal test. Bars represent mean ± standard error of the mean (SEM) latency (in s) to withdraw from a radiant heat stimulus positioned under the ventral hind paws (right and left hind paw data combined). (b) Response of B6 and *e/e* mutants on the 49 °C tail-withdrawal test to systemic injection of various doses (5–15 mg kg^{-1}, subcutaneous) of the selective μ-opioid agonist (and morphine metabolite), morphine-6β-glucuronide (M6G). Symbols represent mean ± SEM percent of total analgesia (based on area under the time–effect curve) over a 300-min testing period postdrug administration. (c) Baseline tolerance to electrical current (10 Hz; 0.1 ms; increased by 0.5-mA steps) applied to the skin in men and women with functional (0 or 1 variant) or nonfunctional (2+ variants) MC1Rs. Bars represent mean ± SEM tolerated stimulus intensity. (d) Influence of *MC1R* genotype on M6G analgesia (0.3 mg kg^{-1}, intravenous) in men and women. Subjects were studied as described in detail in Mogil J. S. *et al.* (2005a). Bars represent mean ± SEM analgesia as expressed as area under the time–effect curve (AUEC relative to baseline current shown in (c)). *$P < 0.05$ compared to other genotype. Adapted from Mogil, J. S. *et al.* 2005a. Melanocortin-1 receptor gene variants affect pain and μ-opioid analgesia in mice and humans. J. Med. Genet. 42, 583–587.

study than another. Liem E. B. and colleagues studied women only, whereas Mogil J. S. and colleagues studied men and women. Most importantly, perhaps, Liem E. B. and colleagues compared phenotypes (women with dark or red hair) whereas Mogil J. S. and colleagues compared *MC1R* genotypes (subjects with functional or nonfunctional MC1Rs). It is not the case that all redheads are so because of inheritance of *MC1R* variants (see Section 5.16.2 above); that needs to be determined empirically by sequencing. Thus it is possible that some subjects in Liem E. B. *et al.* (2005) were misclassified in their inferred genotype.

Finally, a human genetic association study has revealed a possible association with *MC1R* variants and vulvar vestibulitis, with sufferers 3.5-fold more likely to carry loss-of-function alleles at the *MC1R* (Foster, D. C. *et al.*, 2004). It is unclear whether this risk is related to altered pain processing or, as suggested by the authors, to the known anti-inflammatory role of MC1Rs.

5.16.6 Future Directions

It is obvious that future work is needed to resolve the true directions of *MC1R* genotypic effect on pain and pain inhibition phenotypes, and to clarify which phenotypes are sex-specific and which are not. Nonetheless, the fact that a gene like *MC1R* would be involved in pain, analgesia, or anesthesia should be considered quite a surprise. It does not appear on any lists of highly probable candidate genes for mediating pain traits (Belfer, I. *et al.*, 2004), and was considered by many to be a gene whose function was already annotated, or solved. The unearthing of *MC1R*'s role in this particular biological domain highlights the advantages for gene discovery of both mouse genetic linkage mapping and bedside-to-bench strategies.

Glossary

allodynia, hyperalgesia Hyperalgesia denotes increased pain generated by a stimulus that is normally painful and excites nociceptors. It has a peripheral (sensitization of nociceptors) and/or a central component (sensitization of central neurons, e.g., in the dorsal horn of the spinal cord). Allodynia is pain generated by stimuli that activate low-threshold mechanoreceptors (mechanical allodynia) or cold receptors (cold allodynia). The mechanism of allodynia is central (central sensitization generated by persistent excitation of nociceptors). Secondary allodynia is pain elicited by stimulation of low-threshold mechanoreceptors in an area of skin that surrounds a territory with sensitized nociceptors (e.g., generated by inflammation) (Merskey, H. and Bogduk, H., 1994; Meyer, R. A. *et al.*, 2005).

causalgia See Chapter Complex Regional Pain Syndromes.
complex regional pain syndrome See Chapter Neuropathic Pain: Clinical.
enteric nervous system The enteric nervous system (Jänig, W., 2006).
homeostasis The maintenance of physiological parameters such as concentration of ions, blood glucose, arterial blood gases, and body core temperature in a narrow range and around predetermined set-points is called homeostasis. Homeostatic regulation involves autonomic systems, endocrine systems, and the respiratory system (Jänig, W., 2006).
neuropathic pain See Chapters Neuropathic Pain: Basic Mechanisms (Animal) and Complex Regional Pain Syndromes.
referred pain Pain from a particular visceral organ or a particular deep somatic structure is perceived to arise from the body surface (skin), from deep somatic structures, or from other viscera. The area or deep body structures where the pain is referred to is innervated by nerves of the same spinal segments as the affected deep body structures (Giamberardino, M. A., 1999; Jänig, W., 1993; Jänig, W. and Häbler, H. J., 2002).
sympathetic block, sympathectomy See Chapter Sprouting in Dorsal Root Ganglia.
sympathetically maintained pain (SMP) See Chapter Complex Regional Pain Syndromes.
sympatho-adrenal system The sympatho-adrenal system is the adrenal medulla and its innervation by sympathetic preganglionic neurons. The adrenal medulla consists of cells that release either adrenaline or noradrenaline upon impulses in the preganglionic neurons. The sympatho-adrenal system is functionally distinct from the various types of sympatho-neural systems (Jänig, W., 2006).
viscero-somatic convergent neurons (dorsal horn of the spinal cord) See Chapter Spinal Cord Mechanisms of Hyperalgesia and Allodynia.

5.17.1 Introduction

Research on the relationship between the autonomic nervous system and pain is a controversial field with many interesting facets that are important from the biological, pathobiological, and clinical point of view. (I prefer to use the terms biology and pathobiology, instead of physiology and pathophysiology, because they include physiological, morphological, biochemical, and molecular aspects.) I will discuss this field in a broad context and focus mainly on the sympathetic nervous system. I will argue that the peripheral sympathetic noradrenergic neuron may have, in addition to its conventional function to transmit signals generated in the brain to peripheral target cells (e.g., smooth muscle cells, secretory epithelia, heart cells, and neurons of the enteric nervous system), quite different functions that are directly or indirectly related to protection of body tissues and pain. These functions have not been studied as extensively as those related to the regulation of autonomic target cells (Jänig, W., 2006). The parasympathetic nervous system is not involved in the generation of pain, yet it may also be important in protection of body tissues (e.g., the gastrointestinal tract (GIT)). Vagal afferents are involved in integrative aspects of pain, hyperalgesia, and inflammation. This is discussed elsewhere (Jänig, W., 2005; Jänig, W. and Levine, J. D., 2006) and summarized in Jänig W. (2007).

The topic *Autonomic Nervous System and Pain* cannot be reduced to peripheral local processes in which peripheral nociceptive afferent fibers (sensitization of nociceptors and generation of ectopic impulses after nerve lesion), sympathetic fibers, and nonneural cells (e.g., cells of the immune system and the vasculature) are involved. The question to be asked is: How are the cellular and subcellular processes that lead to ongoing pain, allodynia, and hyperalgesia in neuropathic pain and inflammatory pain orchestrated by the brain in the continuous protection of the body against agents from outside as well as from within the body? The brain is an important player to organize and control these protective body reactions via neuroendocrine (hypothalamo-pituitary-adrenocortical and sympatho-adrenal) and autonomic (preferentially the sympathetic) systems. Feedback to the brain occurs via various signaling molecules (e.g., interleukines), hard-wired nociceptive afferents, and other afferent neurons (Figure 1). Table 1 lists different functions of the sympathetic nervous system related to pain and protection of body tissues in biological and pathobiological

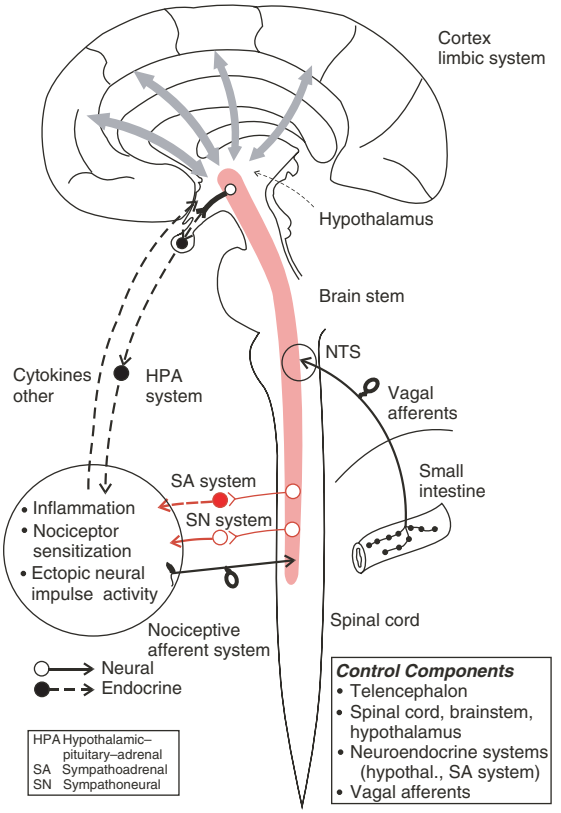

Figure 1 Spinal cord, brainstem, and hypothalamus contain neuronal circuits (pink shaded area) that modulate nociceptor sensitivity, inflammation, and ectopic activity in lesioned afferent neurons in the periphery of the body via the sympatho-adrenal (SA) system, the sympatho-neural system, and the hypothalamic–pituitary–adrenal (HPA) system. Feedback information from the peripheral inflammatory process occurs via nociceptive primary afferent neurons and cytokines. Abdominal vagal afferents signal events from the inner defense line of the body (GALT, gut-associated lymphoid tissue) to the lower brainstem (NTS, nucleus tractus solitarii). The telencephalon controls inflammation and sensitivity of nociceptors via the circuits in the neuraxis (see shaded double arrows).

conditions. It shows that peripheral as well as central mechanisms have to be considered and that the topic includes not only pain and hyperalgesia but also neural and neuroendocrine regulation of inflammation and the immune system.

The integration of the control of protective neural, endocrine, and immune mechanisms occurs in the brain (brainstem, hypothalamus, limbic system, and neocortex). Perception of sensations, feeling of emotions, autonomic, endocrine, and somatomotor responses are coordinated and are, therefore, parallel readouts of the central representations, although the evolvement of feelings of emotions may require explicitly the afferent feedback from body responses generated by the efferent neural autonomic and somatomotor signals (Damasio, A., 2003). These central representations act back on the peripheral tissues, the immune and nociceptive primary afferent neurons, via the endocrine and autonomic nervous systems (Figure 1). The central circuits are also the origin of illness responses that include aversive feelings, pain, and hyperalgesia. This central integration is related or identical to the integrative processes, involving neuroendocrine, immune, and neural systems, occurring during environmental challenges such as viral and bacterial infection (Arkins, S. *et al.*, 2001; Miller, A. H. *et al.*, 2001). Thus, the autonomic nervous system is one component in the generation of pain and protective body reactions that are organized and regulated by the brain and disease occurs when this neural regulation fails.

I will distinguish three aspects of the topic Sympathetic nervous system and pain (Table 1):

1. Reactions of the sympathetic nervous system during pain. This includes the autonomic integrated and adaptive reactions during pain, reflexes to noxious stimulation, and reactions mediated by sympathetic systems in referred zones.
2. Coupling (cross-talk) from sympathetic (noradrenergic) neurons to afferent neurons in the generation of pain. Four broad categories of coupling will be discussed: Direct coupling related to excitation of the sympathetic postganglionic neurons and release of noradrenaline; indirect coupling related to influence of inflammatory processes by the sympathetic nervous system; coupling independent of excitation and noradrenaline release by sympathetic neurons. A fourth category is the effect of adrenaline released by the adrenal medulla on the sensitivity of nociceptors.
3. Sympathetic nervous system and central mechanisms. Based on observations made on patients and animal experimentation, it is likely that activity in sympathetic noradrenergic neurons or in the sympatho-adrenal system, both generated in the brain, contributes directly or indirectly to pain. This central aspect includes the various forms of sympathetic afferent coupling discussed before.

The role of the sympathetic nervous system and its transmitters in chronic inflammation (such as rheumatoid diseases) or in systemic chronic pain diseases (e.g., fibromyalgia) and its interaction with the peptidergic afferent innervation as well as the

Table 1 Sympathetic nervous system and pain

Reactions of the sympathetic nervous system in pain[a]
Protective spinal reflexes
Fight, flight, and quiescence organized at the level of the periaqueductal gray
Hyperalgesia and sympathetically mediated changes in referred zones during visceral pain
Role of the sympathetic nervous system in the generation of pain[b]
Sympathetic–afferent coupling in the periphery
Coupling after nerve lesion (noradrenaline, α-adrenoceptors)
Coupling via the micromilieu of the nociceptor and the vascular bed
Sensitization of nociceptors mediated by sympathetic terminals independent of excitation and release of noradrenaline
Sensitization of nociceptors initiated by cytokines or nerve growth factor and mediated by sympathetic terminals
Sympatho-adrenal system and nociceptor sensitization
Sympathetic nervous system and central mechanisms[c]
Control of inflammation and hyperalgesia by sympathetic and neuroendocrine mechanisms
Complex regional pain syndrome and sympathetic nervous system
Immune system and sympathetic nervous system
Rheumatic diseases and sympathetic nervous system
Systemic chronic pain (e.g., fibromyalgia) and sympathetic nervous system

hypothalamo-pituitary-adrenal (HPA) system will not be discussed. We are at the beginning of the experimental investigation of these control mechanisms (Straub, R. H. and Härle, P., 2005; Straub, R. H. *et al*., 2005; Vierck, C. J. Jr., 2006).

5.17.2 Neurobiology of the Autonomic Nervous System and Pain

The peripheral autonomic nervous system is by definition an efferent system consisting of many functionally distinct pathways that transmit the impulse activity from the spinal cord or brainstem to the effector cells. These pathways are separate from each other and functionally distinct with respect to the effector cells, as is the impulse transmission in the autonomic ganglia and at the neuroeffector junctions to the effector cells. Each peripheral sympathetic or parasympathetic pathway is connected to distinct neuronal networks in the spinal cord, brainstem, and hypothalamus that generate the typical discharge patterns in the autonomic neurons and are responsible for the precise regulation of the target organs (cardiovascular regulation, thermoregulation, regulation of pelvic organs, regulation of GIT, and so forth). The autonomic regulations are represented in these central networks. The anatomical, histochemical, and functional organization of the autonomic nervous system, in particular of the sympathetic nervous system, in the periphery and in the brain, mostly receives insufficient attention in studies of the functioning of this system under pathobiological conditions. I emphasize three points (Jänig, W. and McLachlan, E. M., 2002; Jänig, W., 2006): First, the sympathetic nervous system is functionally as well differentiated as the parasympathetic nervous system. It does not react as a unitary system under normal physiological conditions. Second, the terms sympathetic and parasympathetic are defined anatomically and not functionally. Thus, to use these terms functionally is misleading. Third, the long-held view that sympathetic and parasympathetic nervous system function universally antagonistically is also misleading. Both systems complement each other in their functions.

5.17.2.1 Reactions of the Sympathetic Nervous System in Pain

Any acute, but possibly also chronic tissue-damaging stimulus affects the sympathetic nervous system. Neurons of sympathetic systems exhibit generalized and specific reactions to these stimuli. The generalized reactions probably occur only in certain types of sympathetic system (e.g., muscle vasoconstrictor, visceral vasoconstrictor, sudomotor neurons, or sympathetic cardiomotor neurons) but are weak or absent in other systems (e.g., sympathetic systems to pelvic

organs). They are organized in spinal cord, brainstem (medulla oblongata and mesencephalon), and hypothalamus and can be conceptualized as component parts of the different patterns of defense behavior, such as confrontational defense, flight, or quiescence (Figure 2). Confrontational defense and flight are typical of an active defense strategy when animals encounter threatening stimuli that are potentially injurious for the body, the former potentially leading to fight and the latter to forward avoidance. Both patterns are represented in the lateral and dorsolateral periaqueductal gray of the mesencephalon, activated from the body surface or cortex, and associated with endogenous nonopioid analgesia, hypertension, and tachycardia. Quiescence is similar to the natural reactions of mammals to serious injury and chronic pain occurring particularly in the deep and visceral body domains. It is represented in the ventrolateral periaqueductal gray, activated from the deep (somatic and visceral) body domains, and consists of hyporeactivity, hypotension, bradycardia, and an endogenous opioid analgesia. These stereotyped preprogrammed elementary behaviors and their association with the endogenous control of analgesia enable the organism to cope with dangerous situations that are always accompanied by pain or impending pain. The dorsolateral, lateral, and ventrolateral columns of the periaqueductal gray have distinct reciprocal connections with the autonomic centers in the lower brainstem and hypothalamus that differentially regulate the activity in neurons of the autonomic pathways. They are under differential

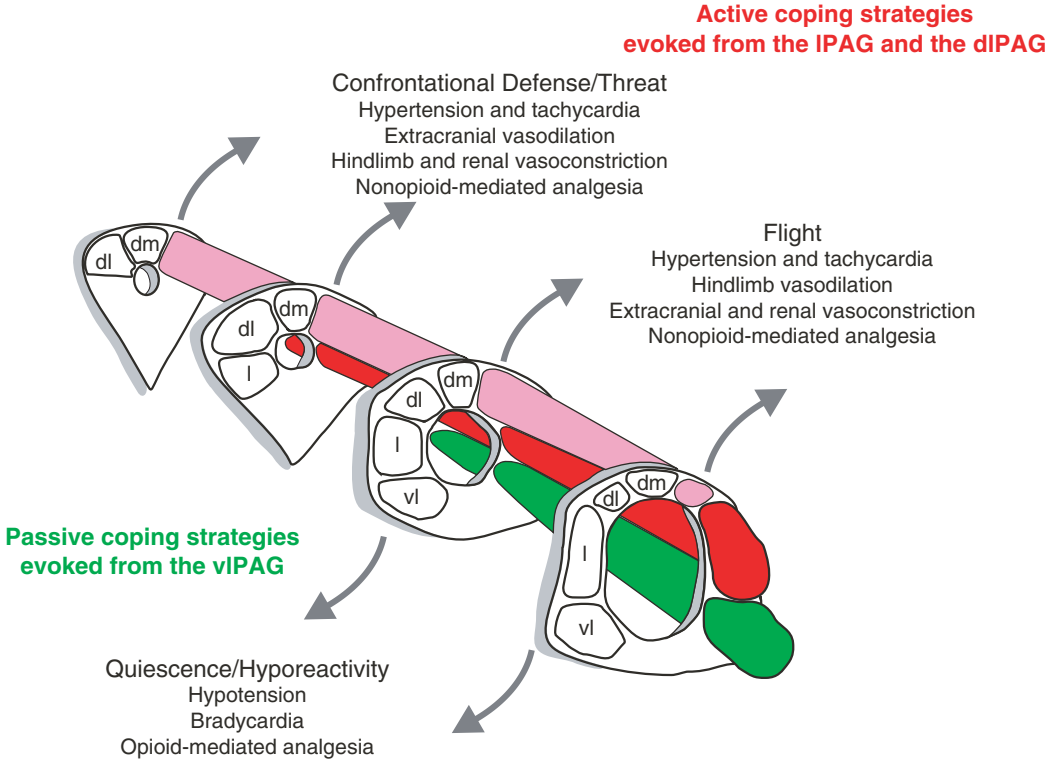

Figure 2 Representation of defense behaviors in the dorsolateral, lateral, and ventrolateral periaqueductal gray. Schematic illustration of the dorsolateral (dl), lateral (l), and ventrolateral (vl) columns within the rostral, intermediate, and caudal periaqueductal gray (PAG). The dorsomedial neural PAG columns are indicated too. Stimulation of neuron populations in the dlPAG, lPAG, and vlPAG by microinjections of the excitatory amino acid glutamate that excites only cell bodies of neurons but not axons evokes distinct defense behaviors: Confrontational defense is elicited from the rostral portion of the dlPAG and lPAG; flight is elicited from the caudal part of the dlPAG and lPAG; quiescence (cessation of spontaneous motor activity) is elicited from the vlPAG in the caudal portion of the PAG. These defense behaviors include typical autonomic cardiovascular reactions (changes of blood pressure, heart rate, and blood flows) and sensory changes (nonopioid- or opioid-mediated analgesia). The representations of confrontational defense and flight are the basis for active coping strategies produced by the cortex. The representation of quiescence is the basis for passive coping strategies produced by the cortex. Modified from Bandler R. and Shipley M. T. (1994) and Bandler R. *et al.* (2000b).

control of the medial and orbital prefrontal cortex and other telencephalic centers (Bandler, R. and Shipley, M. T., 1994; Bandler, R. *et al.*, 2000a; 2000b; Keay, K. A. and Bandler, R., 2004).

There also exist more localized reactions of the sympathetic nervous system to noxious stimuli that are organized within the spinal cord and trigeminal nucleus and in the periphery. These localized reactions are reflected in various somato-sympathetic and viscero-sympathetic reflexes, the afferent neurons of these reflexes are nociceptive (skin, deep somatic tissues, and viscera) and the efferent neurons sympathetic innervating blood vessels (in skin, deep somatic tissues, and viscera), sweat glands, erector pili muscles, enteric nervous system, or other effectors in the viscera. Both afferent neurons and efferent pathways are synaptically connected by various groups of interneurons, establishing circuits that probably are the basis of the changes occurring in referred zones during chronic stimulation of deep nociceptive primary afferents (see below). For example, cutaneous vasoconstrictor neurons exhibit distinct inhibitory reflexes to noxious stimuli of the territories innervated by these neurons.

The hypothalamo-mesencephalic and the spinal level of integration are presumably protective under normal biological conditions and are associated with the activation of the hypothalamo-pituitary adrenocortical system (Jänig, W., 2006).

5.17.2.2 Visceral Afferents, Autonomic Nervous System, and Pain

Visceral organs in the thoracic, abdominal, and pelvic cavities are innervated by two sets of extrinsic primary afferent neurons: spinal visceral afferent neurons and vagal visceral afferent neurons (the latter also including afferent neurons from arterial baro- and chemoreceptors that project through the glossopharyngeal nerve). Spinal visceral afferent neurons have their cell bodies in the dorsal root ganglia (DRG) and vagal afferent neurons in the inferior (nodose) ganglion of the vagus nerve (a few in the superior (jugular) ganglion of the vagus nerve and some arterial baro- and chemoreceptor afferents in the petrosal ganglion). Visceral afferent neurons are involved in specific organ regulations, multiple organ reflexes, neuroendocrine regulations, and visceral sensations (including visceral pain), shaping and eliciting emotional feelings and other functions. They monitor the inner state of the body and serve to maintain homeostasis and to adapt the internal milieu and the regulation of the organs to the behavior of the organism. They are anatomically and functionally closely associated with the autonomic nervous system. However, they should not be labeled sympathetic, parasympathetic, or autonomic afferent neurons. These functional labels are misleading since they imply that the visceral afferent neurons have functions that uniquely pertain to the sympathetic or parasympathetic autonomic nervous system, the exception being that afferent neurons of the enteric nervous system are per definition enteric afferent neurons. No functional, morphological, histochemical, or other criteria do exist to associate any type of visceral afferent neuron with only one autonomic system (Jänig, W., 2006).

Usually, vagal afferent neurons are described and characterized by adequate physiological stimuli exciting them and by the main reflexes associated with the cardiovascular system, respiratory system, GIT, or other regulatory systems (Undem, B. J. and Weinreich, D., 2005). However, several observations show that groups of vagal afferents innervating visceral organs in the thoracic and abdominal cavity are involved in the control of nociception and pain, in neuroendocrine control of nociceptors, in the control of inflammation, and in the control of general protective body reactions including illness responses. Subgroups of vagal afferent neurons may signal events from visceral organs, in particular those occurring at the internal defense line of the body in the GIT represented in the liver and in the small intestine (which contains the largest immune system of the body, the gut associated lymphoid tissue (GALT)), to the central nervous system that triggers protective body reactions not only in the viscera but also in the superficial and deep somatic body tissues (see Chapters Visceral Pain; Vagal Afferent Neurons and Pain; Jänig, W., 2005). These vagal afferent neurons may be activated or sensitized by cellular processes of these inner body defense lines and their signaling molecules. Stimulation of vagal afferents may generate sickness behavior that is characterized by several protective illness responses (immobility, decreased social interaction, decrease in food intake and of digestion, formation of taste aversion against novel food, loss of weight, fever, increase of sleep, change in endocrine functions (e.g., of the activation of the hypothalamic–pituitary system), malaise; Watkins, L. R. *et al.*, 1995; Maier, S. F. and Watkins, L. R., 1998; Watkins, L. R. and Maier, S. F., 1999; 2000; Goehler, L. E. *et al.*, 2000), activates the inhibitory control of nociceptive impulse transmission

in the spinal and trigeminal dorsal horn (Foreman, R. D., 1989; Randich, A. and Gebhart, G. F., 1992; Jänig, W., 2005), inhibits nociceptive–neuroendocrine reflex circuits that control inflammation (via the sympatho-adrenal system and the hypothalamic–pituitary system (Green, P. G. *et al.*, 1995; 1997; Jänig, W. *et al.*, 2000; Miao, F. J.-P. *et al.*, 2000; 2001)), and inhibits the central circuits that control via the adrenal medulla and release of adrenaline the sensitivity of nociceptors (Khasar, S. G. *et al.*, 1998a; 1998b; Jänig, W. *et al.*, 2000; Khasar, S. G. *et al.*, 2003; Jänig, W. *et al.*, 2006; see below). For these hypothetic functions of vagal afferents involving neuroendocrine and autonomic systems, in the protection of the body, an umbrella concept in the frame of body protection, pain, and inflammation has to be formulated. This has to include the central circuits (see Jänig, W., 2005; Jänig, W. and Levine, J. D., 2006).

5.17.2.3 Hyperalgesia and Sympathetically Mediated Changes in Referred Zones During Visceral Pain

Chronic stimulation of spinal afferents from visceral organs may elicit pain, hyperalgesia, and allodynia in the referred zones of the body surface and of the deep somatic domain (skin, subcutaneous tissue, musculature, tendons, fascia, and bones). Hyperalgesia and allodynia that are elicited in the superficial and deep somatic domains by visceral diseases are equivalent to secondary hyperalgesia and allodynia in the skin caused by ongoing activity in polymodal C-nociceptors (Cervero, F. and Jänig, W., 1992; Vecchiet, L. *et al.*, 1993). The degree and spatial spread of referred pain, hyperalgesia, and allodynia depend on the intensity and duration of the visceral stimulation and the type of visceral organ. They are abolished after blockade of the impulse traffic in spinal visceral afferents to the spinal cord. They may be generated by sensitization of neurons in the spinal cord that are involved in the generation of sensations (e.g., spinothalamic tract neurons), in the descending control of spinal circuits (e.g., spinal neurons projecting to the brainstem or interneurons mediating signals of the endogenous control system), and in the regulation of sympathetic target organs and skeletal musculature constituting spinal and supraspinal viscero-sympathetic and viscero-somatic reflex pathways (Figure 3). The most likely candidate of these neurons is the broad class of viscero-somatic convergent neurons in the spinal cord (Cervero, F. and Jänig, W., 1992; Cervero, F., 1995; Bielefeldt, T. K. and Gebhart, G. F., 2006).

Little attention has been given to the generation of autonomic changes (reflected in changes of blood flow, sweating, and piloerection) and of trophic changes in the skin and its appendages, subcutis, joint capsules, and fascia of the referred hyperalgesic (Head's) zones during visceral diseases (Jänig, W. and Morrison, S. F., 1986). These changes are very variable between individuals but reported to be relatively stable for each individual. The clinical diagnosis of a visceral disease (e.g., in the GIT, of the evacuative organs, or of the heart) may be predicted from these changes with a probability of about 70% (Beal, M. C., 1983; Cox, J. M. *et al.*, 1983; Beal, M. C., 1985; Nicholas, A. S. *et al.*, 1985).

It is important to note that the trophic changes occur in regions that are outside of the site of injury or trauma, that the first sign of the trophic changes is probably the edema, and that the severe signs of these changes develop relatively slowly and late. These changes are believed to be generated by the segmental sympathetic outflow to the visceral reference zones at the trunk. However, the trophic changes in the referred zones may also or additionally be related to changes in the retrograde axonal transport in afferent neurons that innervate the referred zones (see discussion in Jänig, W., 1993). We need more reliable and quantitative data about the changes occurring in the referred somatic zones in patients with various visceral diseases to develop testable hypotheses.

The mechanisms explaining referred visceral pain and the changes observed in the referred zones that probably are associated with the sympathetic neurons are barely understood. Classical central theories trying to explain referred visceral pain are the convergence-projection theory of Ruch T. C. (1965) and the convergence-facilitation theory of MacKenzie, J. (1920). (The convergence-projection theory of Ruch T. C. (1965) is based on the concept that spinal neurons in the dorsal horn projecting to the thalamus obtain convergent synaptic input from primary afferent neurons innervating viscera or somatic body tissues. The telencephalon localizes the pain generated by activity in visceral afferents erroneously into somatic tissues of the corresponding dermatomes, myotomes, and sklerotomes. The convergence-facilitation theory of MacKenzie J. (1920) proposes that afferent inputs from the viscera to the spinal cord are not directly related to pain sensation but that they produce a generalized increase of excitability in the area of the spinal cord, which is related to the respective visceral organ generating

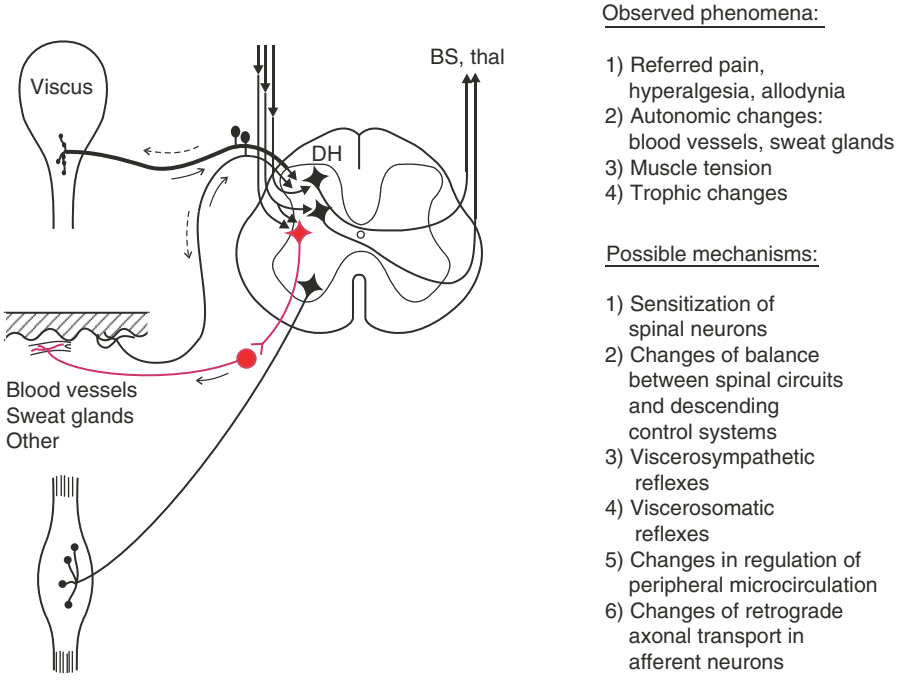

Figure 3 Observed phenomena generated in referred zones during visceral trauma (e.g., inflammation) and the putative mechanisms underlying these changes. Sympathetic pathways (indicated in red) mediate changes of blood flow, sweating, or piloerection and possibly changes of tissue structure (edema, trophic changes). The mechanisms underlying the latter are not understood. Continuous arrows, excitation; dashed arrows, retrograde axonal transport. BS, brainstem; DH, dorsal horn; thal, thalamus. Modified from Jänig W. (1993).

an irritable focus. This was to promote activity in neurons projecting to the thalamus and obtaining convergent synaptic input from somatic tissue (leading to referred pain and referred hyperalgesia), in motoneurons (leading to muscle spasms), and in sympathetic neurons (leading to autonomic changes in the referred zones) (Ness, T. J., 1995).) However, both theories explain the mechanisms underlying referred pain rather incompletely and the mechanisms of the other changes in the referred zones in which the sympathetic nervous system is involved not at all (see Ness, T. J. and Gebhart, G. F., 1990; Jänig, W. and Koltzenburg, M., 1993; Vecchiet, L. *et al.*, 1993; Ness, T. J., 1995; Giamberardino, M. A., 1999, for discussion). It is suggested that persistent sensitization and activation of visceral afferent neurons (e.g., during chronic inflammation) sensitize the second-order viscero-somatic convergent neurons in the dorsal horn of the spinal cord that can be synaptically activated from viscera as well as from somatic tissues (skin and deep somatic tissues). However, it has not been convincingly demonstrated that these viscero-somatic convergent neurons can be sensitized by activity in visceral afferents (Herrero, J. F. *et al.*, 2000; Jänig, W. and Häbler, H. J., 2002).

This invites speculation that not only spinal mechanisms but also, or in particular, supraspinal mechanisms are responsible to explain the phenomenology of referred pain. Supraspinal mechanisms controlling synaptic impulse transmission in the dorsal horn are inhibitory or excitatory (Urban, M. O. and Gebhart, G. F., 1999; Porreca, F. *et al.*, 2002). These mechanisms are represented in the periaqueductal gray, the caudal raphe nuclei, the ventromedial medulla, and the dorsolateral pontine tegmentum (Fields, H. L. *et al.*, 2006). They do control not only nociceptive impulse transmission in the dorsal horn but also various autonomic regulations and possibly neuroendocrine regulations (Mason, P., 2001) and are in turn under the control of the cerebral hemispheres. Thus, the reference of visceral affections (e.g., chronic inflammation in the viscera) into somatic zones may be dependent on these endogenous protective control systems. These referred phenomena (that include sensory, autonomic, and motor changes) may therefore be the biological

expression of protective mechanisms operating in spinal cord and brainstem in the somatic body domains.

5.17.3 Role of the Sympathetic Nervous System in the Generation of Pain

5.17.3.1 Clinical Background: Sympathetically Maintained Pain

Pain being dependent on activity in sympathetic neurons is called sympathetically maintained pain (SMP). SMP is a symptom and includes generically spontaneous pain and pain evoked by mechanical or thermal stimuli. It may be present in the complex regional pain syndrome (CRPS) type I and type II and in other pain syndromes. The idea about the involvement of the (efferent) sympathetic nervous system in the generation of pain is based on various clinical observations that have been documented in the literature since tens of years (Bonica, J. J., 1990). Representative for these multiple observations on patients with pain in which the sympathetic nervous system is causally involved are experimental investigation on patients with CRPS who had SMP (1–4) and other less well-controlled observations on patients with pain.

1. Spontaneous pain, mechanical allodynia, and cold allodynia in the upper extremity of patients with CRPS II, which are alleviated by stellate ganglion block, can be rekindled, under the condition of sympathetic block, by injection of noradrenaline into the skin area that was painful before sympathetic block (Figure 4; Torebjörk, H. E. *et al.*, 1995). By the same token, it has been shown in patients with causalgia, who had been successfully treated either by sympathectomy or by transcutaneous nerve stimulation, that ionophoretic application of noradrenaline to the previously causalgic skin area rekindles spontaneous pain and mechanical allodynia (Wallin, G. *et al.*, 1976). Rekindling of spontaneous and evoked pain or enhancement of both by noradrenaline injected into the skin area, which was painful before sympathetic block or before successful treatment, took 10 min or longer to develop (Figure 4b). This long latency indicates that noradrenaline does not act possibly directly on the afferent fiber terminals, but by some unknown mechanism via changes in the micromilieu of the nociceptors.
2. Intradermal injection of noradrenaline in physiologically relevant doses in patients with SMP evokes greater pain in the affected limb regions than in the contralateral unaffected limb or in control subjects. Most patients whose pain increased after injection of noradrenaline in the affected extremity report a decrease in pain following systemic injection of the α-adrenoceptor blocker phentolamine (Ali, Z. *et al.*, 2000; see also Arnér, S., 1991).
3. In CRPS type I patients with SMP, pain is relieved after blockade of sympathetic activity to the affected extremity by a local anesthetic applied to the appropriate sympathetic paravertebral ganglia. This pain relief lasts significantly longer than the short-lasting pain-relieving effect of saline injected close to the same paravertebral ganglia (control injection) in the same group of CRPS patients showing that the real pain-relieving effect generated by blockade of sympathetic activity can be discriminated from the placebo effect and the duration of pain relief outlasts the duration of conduction block generated by the local anesthetic by an order of magnitude (Price, D. D. *et al.*, 1998; see Figure 15).
4. Pain (spontaneous, mechanical allodynia) in the hand of chronic CRPS I patients with SMP, which is clamped to a temperature of about 36 °C, is enhanced when activity in cutaneous vasoconstrictor neurons is increased by central cooling (Figure 5), yet not in chronic CRPS I patients without SMP (Baron, R. *et al.*, 2002). This experiment demonstrates that an increase of activity in sympathetic neurons by a physiological intervention (central cooling) can increase pain, possibly independent of a vascular component. An important side effect of this experimental investigation is that the peripheral mechanisms underlying SMP in CRPS I patients occur mainly in deep somatic tissues.
5. Injection of adrenaline around a stump neuroma that has developed long after limb amputation may be intensely painful (Chabal, C. *et al.*, 1992).
6. In patients with CRPS II, but not in those with hyperhidrosis, intraoperative electrical stimulation of the sympathetic chain may increase spontaneous pain (Walker, A. E. and Nulsen, F., 1948; White, J. C. and Sweet, W. H., 1969).
7. In patients with SMP phentolamine (α-adrenoceptor blocker) given intravenously may relieve pain but not propranolol (β-adrenoceptor blocker) (Arnér, S., 1991; Raja, S. N. *et al.*, 1991; Dellemijn, P. L. *et al.*, 1994).

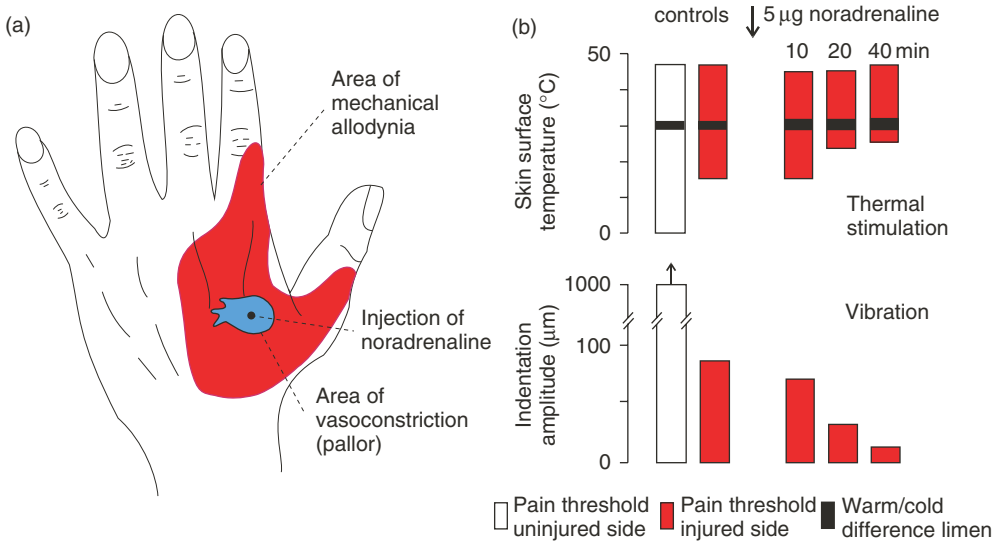

Figure 4 Mechanical and cold allodynia in CRPS type II patients with sympathetically maintained pain (SPM) elicited by intradermal injection of noradrenaline. Noradrenaline was injected intradermally at the site of mechanical and cold allodynia when the patients were temporarily relieved from their pain by a stellate ganglion block with lidocaine (1%) or bupivacaine (0.25%). (a) Area of pallor and mechanical allodynia 20 min after intradermal injection of 2 µg noradrenaline. (b) Sequential quantitative sensory testing of patients before and after intradermal injection of 5 µg noradrenaline during a time without blockade of the stellate ganglion. This patient had mechanical allodynia (indentation amplitude of a mechanical vibration stimulus to evoke pain about 90 µm, *lower panel*) and cold hyperalgesia/allodynia (cold pain threshold about 15 °C, *upper panel*). The mechanical allodynia (further decrease of indentation amplitude to elicit pain) and cold allodynia (further decrease of cold pain threshold) progressively worsened starting approximately 20 min after intradermal injection of 5 µg noradrenaline. Modified from Torebjörk H. E. *et al.* (1995) with permission.

8. In some patients with postherpetic neuralgia, spontaneous pain and mechanical allodynia are enhanced after intracutaneous injection of adrenaline or the α1-adrenoceptor agonist phenylephrine (Choi, B. and Robotham, M. C., 1997).

I recommend to read Mitchell S. W. (1872), Livingston W. K. (1943/1976; here in particular chapters 5, 6, 14, and 15), and Bonica J. J. (1953; Chapter 28). These texts are not only of historical interest (here the literature before 1953 is discussed) but also the reader will find (1) a wealth of carefully reported clinical observations and (2) ideas developed on the basis of these clinical observations that are still quite modern, showing that the progress in this field is not as impressive as it appears to be.

These key experiments conducted on human patients with SMP demonstrate that (1) activation of sympathetic postganglionic neurons can produce pain, (2) blockade of sympathetic activity can relieve the pain, (3) noradrenaline injected intracutaneously rekindles the pain, and (4) α-adrenoceptor blockers or guanethidine (which depletes noradrenaline from its stores) can relieve the pain (Jänig, W. and Baron, R., 2001; 2002; Jänig, W., 2002; Jänig, W. and Baron, R., 2003).

The interpretation of these data is that the nociceptors are excited and possibly sensitized by noradrenaline released by the sympathetic fibers. Either the nociceptors have expressed adrenoceptors or the excitatory effect is generated indirectly, e.g., via changes in blood flow and subsequent ischemia or by other components modulated by sympathetic fibers. The ways of sympathetic afferent coupling to be discussed are illustrated in Figure 6. Sympathetically maintained activity in nociceptive neurons may generate and maintain a state of central sensitization/hyperexcitability, leading to spontaneous pain and secondary evoked pain (mechanical and possibly cold allodynia). This is schematically illustrated in Figure 7.

5.17.3.2 Sympathetically Maintained Pain Following Nerve Lesion Simulated in Behavioral Animal Models

In animals (rats), signs of pain are measured by quantifiable behavioral components, e.g., paw-withdrawal latency to thermal noxious stimulation (heat and cold), frequency and threshold of paw withdrawal to mechanical stimulation, degree of self-mutilation

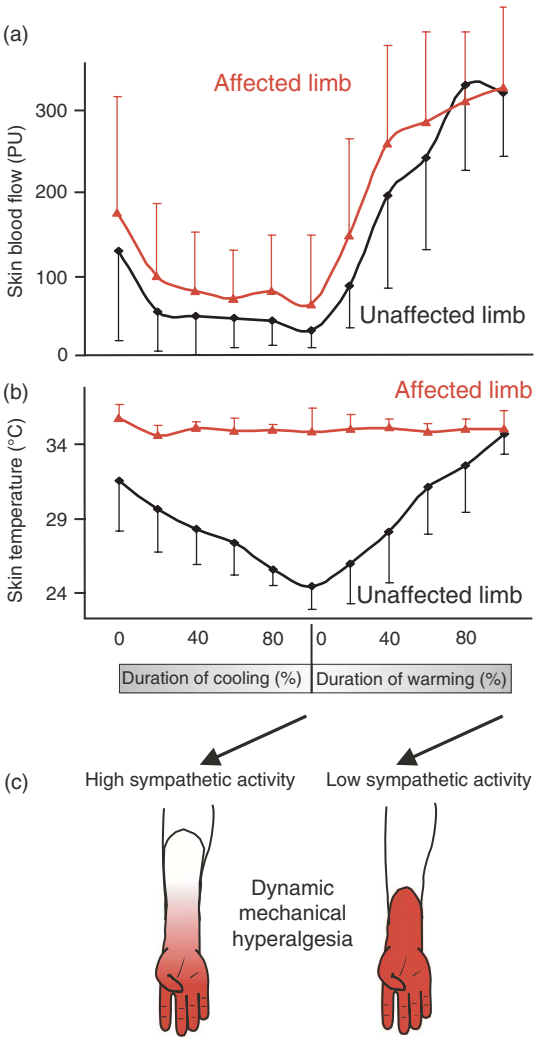

Figure 5 Experimental changes of activity in cutaneous sympathetic vasoconstrictor neurons by physiological thermoregulatory reflex stimuli in 13 complex regional pain syndrome (CRPS) patients. With the help of a thermal suit, whole-body cooling and warming was performed to alter sympathetic skin nerve activity. The subjects were lying in a suit supplied by tubes, in which running water at 12 °C and 50 °C, respectively (inflow temperature), was used to cool or warm the whole body. By these means, sympathetic activity can be switched on and off. (a) High sympathetic vasoconstrictor activity during cooling induces considerable drop in skin blood flow on the affected and unaffected extremity (laser Doppler flowmetry). Measurements were taken at 5-min intervals (mean + SD). (b) On the unaffected side, a secondary decrease of skin temperature was documented. On the affected side, the forearm temperature was clamped at 35 °C by a feedback-controlled heat lamp to exclude temperature effects on the sensory receptor level. Measurements were taken at 5-min intervals (mean + SD). (c) Effect of cutaneous sympathetic vasoconstrictor activity on dynamic mechanical hyperalgesia in one CRPS patient with sympathetically maintained pain (SMP). Activation of sympathetic neurons (during cooling) leads to an increase of the area of dynamic mechanical hyperalgesia. Reprinted with permission from Baron R. *et al.* (2002).

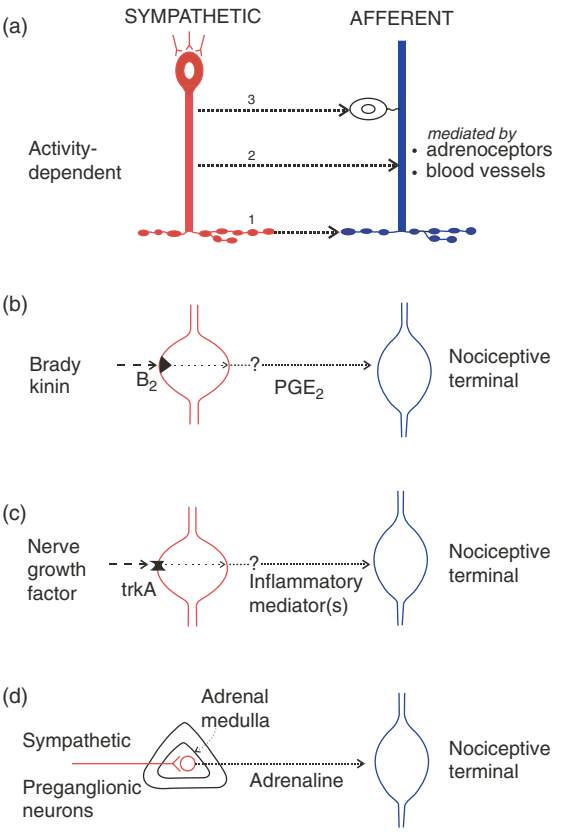

Figure 6 Ways hypothesized to couple sympathetic and primary afferent neurons following peripheral nerve lesion (a) or during inflammation (b–d). (a) These types of coupling depend on the activity in the sympathetic neurons and on the expression of functional adrenoceptors by the afferent neurons or mediation indirectly via the blood vessels (blood flow). It can occur in the periphery (1), in the dorsal root ganglion (3), or possibly also in the lesioned nerve (2). (b) The inflammatory mediator bradykinin acts at B_2 receptors in the membrane of the sympathetic varicosities or in cells upstream of these varicosities, inducing release of prostaglandin E_2 (PGE_2) and sensitization of nociceptors. This way of coupling is probably not dependent on activity in the sympathetic neurons. (c) Nerve growth factor released during an experimental inflammation reacts with the high-affinity receptor trkA, in the membrane of the sympathetic varicosities, inducing release of an inflammatory mediator or inflammatory mediators and sensitization of nociceptors. This effect is probably not dependent on activity in the sympathetic neurons. (d) Activation of the adrenal medulla by sympathetic preganglionic neurons leads to release of adrenaline that generates sensitization of nociceptors. The ? in (b) and (c) indicates that PGE_2 or other inflammatory mediators may be released by cells other than the sympathetic varicosities. Modified from Jänig W. and Häbler H. J. (2000b).

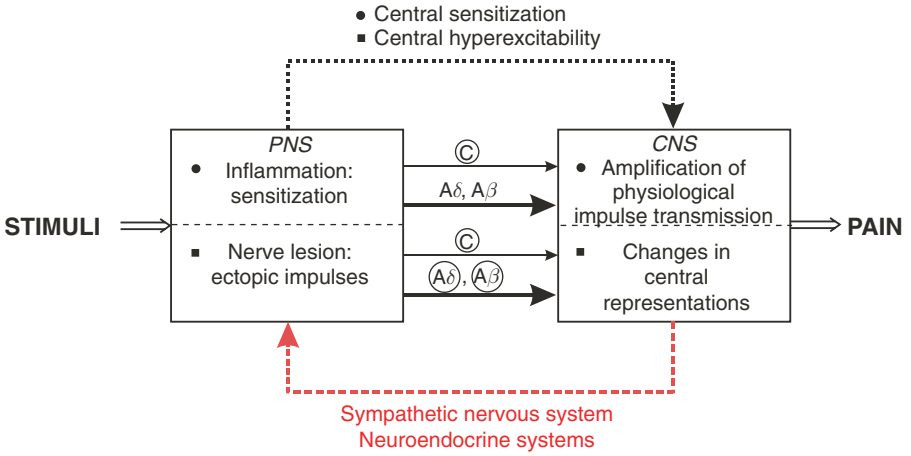

Figure 7 Concept of generation of peripheral and central hyperexcitability during inflammatory pain and neuropathic pain. The upper interrupted arrow indicates that the central changes are generated (and possibly maintained) (a) by persistent activation of nociceptors with C-fibers (e.g., during chronic inflammation) called here central sensitization or (b) after trauma with nerve lesion by ectopic activity and other changes in lesioned afferent neurons called here central hyperexcitability. The lower interrupted arrow indicates the efferent feedback via the sympathetic nervous system and neuroendocrine systems (e.g., the sympatho-adrenal system). Primary afferent nociceptive neurons (in particular those with C-fibers) are sensitized during inflammation. After nerve lesion, all lesioned primary afferent neurons (unmyelinated as well as myelinated ones) undergo biochemical, physiological, and morphological changes that become irreversible with time. These peripheral changes entail changes of the central representation (of the somato-sensory system) that become irreversible if no regeneration of primary afferent neurons to their target tissue occurs. The central changes, induced by persistent activity in afferent nociceptive neurons during inflammation or induced after nerve lesion, are also reflected in the efferent feedback systems that may establish positive feedback loops to the primary afferent neurons.

(autotomy), or spontaneous lifting and licking of paw. These reactions are interpreted as equivalent to mechanical or thermal hyperalgesia or allodynia or spontaneous pain in humans. Behavioral models allow to test whether the sympathetic nervous system contributes to these hyperalgesic/allodynic behaviors or to spontaneous pain behavior. Animals are given clinically relevant nerve lesions, and behavioral experiments are performed before and after interventions aimed at the sympathetic supply of the affected extremity. The strength of these models includes the range of possible experimental manipulations performed at the sympathetic nervous system and the use of different strains of animals or transgenic animals. Quantitative data obtained in these behavioral experiments lead to the formulation of hypotheses that can be tested in reduced experiments *in vivo* and *in vitro* using various methodical approaches.

Several rat models of neuropathic pain involving controlled nerve lesions have been used to determine the contribution of the sympathetic nervous system to neuropathic pain. The results obtained in these experiments are summarized in Table 2. The interventions include surgical or chemical sympathectomy, systemic or local application of adrenoceptor blockers (e.g., phentolamine (α_1,α_2), prazosin (α_1), or yohimbin (α_2)) or of adrenoceptor agonists (e.g., phenylephrine (α_1) and clonidine (α_2)), and intraperitoneal application of guanethidine (that is taken up by the noradrenergic terminals and depletes noradrenaline).

Overall, the results obtained on these rat behavioral models of nerve injury are somewhat disappointing since they did not lead to straightforward answers. Thus, the controversial results on these models provide conflicting evidence on the role of the sympathetic nervous system in generating pain behavior, indicating that behavioral animal models must be designed with utmost care. Small changes in the experimental procedures may create major behavioral changes. Behavioral testing should be performed in a blinded fashion if possible, and the models must be designed in close association with the clinical situation to be certain to test what is intended to be tested. The results of systemic pharmacological interventions (e.g., application of adrenoceptor agonists or antagonists, guanethidine, or chemical sympathectomy with 5-hydroxy-dopamine) do not necessarily allow functional interpretations, partly because of the widespread systemic effects of these agents. Finally, the controversial results obtained from the animal behavior

models may argue that the models do not reflect SMP as defined clinically.

This controversial situation does not mean that behavioral animal models are useless and cannot simulate the clinical situation. On the contrary, we are dependent on the design of these animal models if we want to unravel the mechanisms behind the different types of pathological pain in which the sympathetic nervous system is involved. However, the same model cannot be expected to represent SMP in different groups of patients. Furthermore, the animal models so far tested are related to nerve lesions. Rat models simulating SMP in patients with pain states developing after trauma without nerve lesion (Table 1) practically do not exist (e.g., for patients with CRPS I).

5.17.3.3 Direct Involvement of the Sympathetic Nervous System in the Generation of Pain Following Nerve Trauma

Under physiological conditions, there exists almost no acute influence of sympathetic postganglionic neurons on sensory neurons projecting to skin or deep somatic tissues in mammals. The effects that have been measured under experimental conditions on sensory receptors with myelinated or unmyelinated axons were weak and can in part be explained by changes of the effector organs (erector pili muscles and blood vessels) induced by the activation of sympathetic neurons. These rather negative results do not rule out that noradrenaline or colocalized substances released by the postganglionic terminals have secondary long-term effects on the excitability of sensory receptors although we have no experimental evidence for this (Jänig, W. and Koltzenburg, M., 1991).

5.17.3.3.1 Coupling between lesioned postganglionic and afferent nerve terminals

Coupling may occur between sympathetic fibers and afferent terminals in a neuroma, following nerve section or ligation. Some myelinated as well as unmyelinated nerve fibers in the neuroma can be excited following electrical stimulation of the sympathetic supply or by noradrenaline or adrenaline injected systemically. The coupling has been

observed in young neuromas but less so in old ones, weeks and months after nerve lesion. Furthermore, the frequency of electrical stimulation applied to the sympathetic trunk in order to excite the lesioned afferent nerve fibers was high, generating activity in the sympathetic neurons that does not occurs under physiological conditions (Jänig, W., 2006). This corresponds to the clinical experience showing that neuroma pain is usually not dependent on sympathetic activity. It also corresponds to histological observations showing that catecholamine-containing axon profiles are rare within the neuroma and for several centimeters proximal to it but may be present in the scar tissue around the neuroma), many weeks after cutting and ligating the nerve (McLachlan, E. M., unpublished data). Thus, this coupling is chemical and occurs via noradrenaline acting on α-adrenoceptors, although other mediator substances may also be involved (Jänig, W., 1990). Ephaptic coupling between sympathetic fibers and afferent fibers has so far not been observed in a neuroma (Devor, M. and Jänig, W., 1981; Blumberg, H. and Jänig, W., 1982; 1984; Jänig, W. and Koltzenburg, M., 1991).

The situation is different when afferent and sympathetic fibers are allowed to regenerate to the target tissue. This has been shown experimentally for the chronic situation more than a year after cross-union of nerves (e.g., adaptation of the proximal stump of the sural or superficial peroneal nerve to the distal stump of the tibial nerve, in the cat) and after reinnervation of appropriate and inappropriate target tissues. Now unmyelinated afferent fibers may be vigorously excited by electrical low-frequency stimulation of the sympathetic supply (Häbler, H. J. *et al.*, 1987). Also this excitation is adrenoceptor-mediated (Figure 8). It can be mimicked by adrenaline or noradrenaline and blocked by α-adrenoceptor blockers (e.g., phentolamine).

5.17.3.3.2 Coupling between unlesioned postganglionic and afferent nerve terminals following partial nerve lesion

Intact C-fiber polymodal nociceptors in the skin may develop sensitivity to catecholamines following partial nerve injury. Sympathetic nerve stimulation and noradrenaline may excite the polymodal nociceptors or sensitize them for heat stimuli. The activation and sensitization is already seen 4–10 days after partial nerve lesion and is maintained for at least 150 days. This sympathetic afferent coupling apparently involves the nonlesioned polymodal nociceptive afferent axons that project through the lesion site and nonlesioned postganglionic axons. It is suggested that the unlesioned unmyelinated afferents develop hyper-reactivity to catecholamines following degeneration of the sympathetic postganglionic axons. Expression of adrenoceptors in afferent fibers may be triggered by collateral sprouting of both afferent fibers and postganglionic fibers in the target tissue (Sato, J. and Perl, E. R., 1991). However, sympathetic afferent coupling leading to activation or sensitization of nociceptors requires sympathetic stimulation at high nonphysiological frequencies.

5.17.3.3.3 Coupling in the dorsal root ganglion and collateral sprouting following peripheral nerve lesion

Chemical sympathetic afferent coupling following peripheral nerve lesion (e.g., a spinal nerve, the sciatic nerve, or another hindlimb nerve) may occur proximally to the injury site in the nerve or in the DRG (Figure 6a3). Sympathetic postganglionic fibers reach the spinal nerves via gray rami. Most of these fibers project distally to peripheral target cells, and others project proximally (e.g., to the DRG) and are normally found along blood vessels. This situation changes after an experimental nerve lesion (e.g., transection and ligation of the sciatic nerve in rats). Now many perivascular catecholamine-containing axons of the unlesioned proximally projecting neurons start to sprout in the DRGs that contain somata with lesioned axons. The extent of this collateral sprouting increases with time after nerve lesion. Some somata are partially or almost completely surrounded by varicose catecholaminergic terminals several weeks after nerve lesion; the frequency of these catecholamine-fluorescent structures increases for more than 70 days after nerve lesion. The noradrenergic axons sprout preferentially to axotomized large-diameter afferent cell bodies (McLachlan, E. M. *et al.*, 1993; Chapter Sprouting in Dorsal Root Ganglia).

Neurophysiological experiments on rats with nerve lesion (ligation and transection of a spinal nerve, the sciatic nerve, or other hindlimb nerves) show that afferent neurons projecting in the lesioned nerve can be excited or depressed in their activity affected via the DRG by electrical stimulation of sympathetic neurons and by catecholamines: (1) In the first 2 to 3 weeks after nerve lesion, most A-fiber neurons with spontaneous activity and only very few silent A-fiber neurons are excited. At later time periods, when the catecholaminergic sprouting in the

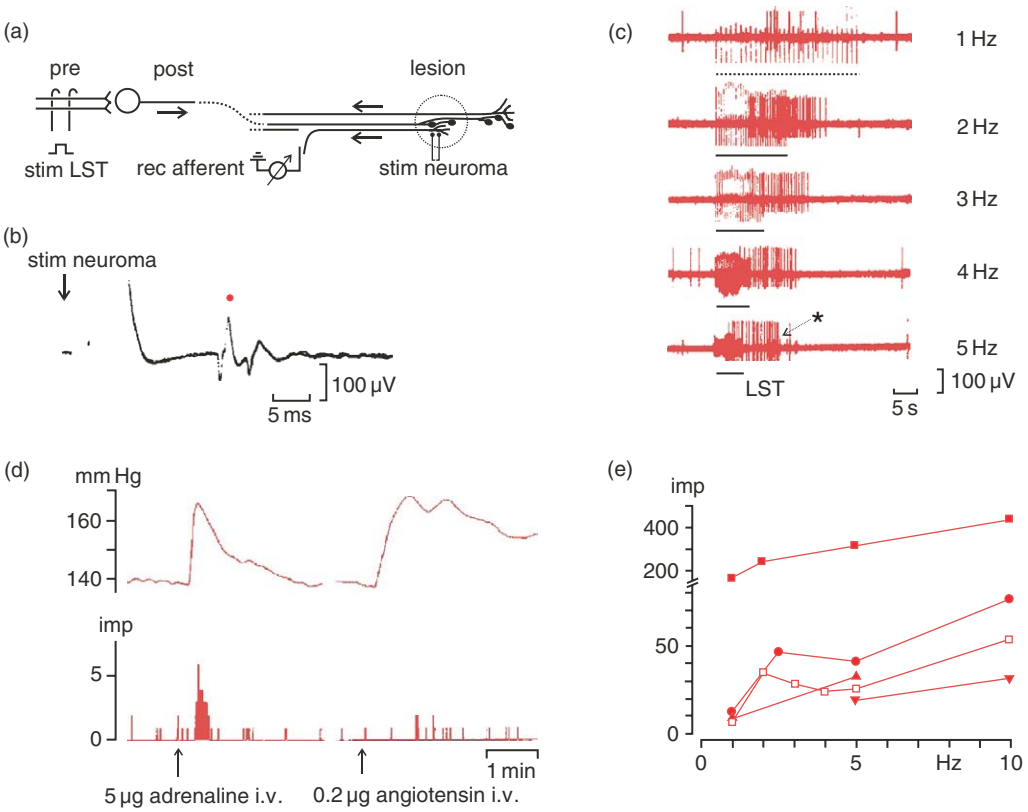

Figure 8 Sympathetic afferent coupling after nerve lesion with subsequent fiber regeneration. Excitation of unmyelinated afferent fibers by electrical stimulation of sympathetic fibers following nerve injury. Unmyelinated primary afferents were recorded in cats 11–20 months following a nerve lesion. The central cut stump of a cutaneous nerve innervating hairy skin (sural or superficial peroneal nerve) had been imperfectly adapted to the distal stump of a transected mixed nerve (tibial nerve). This preparation was designed to mimic the consequences of lesion of a mixed nerve. A neuroma-in-continuity at the lesion site was present and cutaneous nerve fibers had regenerated into skin and deep somatic tissue supplied by the mixed nerve. (a) Experimental setup. post, postganglionic; pre, preganglionic; LST, lumbar sympathetic trunk. (b) The afferent fibers were identified as unmyelinated by electrical stimulation of the neuroma with single impulses. The signal indicated by the dot was recorded from the same afferent fiber as in (c) and (d); the afferent fiber conducted at 1.3 m s^{-1}. (c) Record from a single unmyelinated afferent unit. Supramaximal stimulation of the LST with trains of 30 pulses at 1–5 Hz (trains and stimulation artifacts indicated by bars). Note that the afferent unit had some low rate of ongoing activity (impulses before the trains at 1 and 4 Hz) and a second fiber was activated at 5 Hz stimulation (marked by an asterisk). (d) Adrenaline (5 µg injected i.v.) activated the fiber. Angiotensin (0.2 µg injected i.v.) generated a large increase of blood pressure (MAP, mean arterial blood pressure) but did not activate the afferent fiber. (e) Stimulus response curves for the single unit (□) and four filaments containing two to three (●, ▲/▼) or more than five (■) afferent units. Ordinate scale is the total number of impulses exceeding ongoing activity in response to variable stimulation frequency of the LST. Modified from Häbler H. J. *et al.* (1987).

DRG is more prominent, most spontaneously active A-fiber neurons are inhibited during stimulation of the sympathetic supply but rarely excited. (2) Only very few afferent neurons with unmyelinated axons respond to electrical stimulation of the sympathetic trunk; most of them are inhibited in their activity (McLachlan, E. M. *et al.*, 1993; Devor, M. *et al.*, 1994; Michaelis, M. *et al.*, 1996). (3) The coupling from sympathetic postganglionic fibers to the afferent cell bodies in the DRG probably occurs only to spontaneously active muscle afferent neurons with Aδ-fibers (Michaelis, M. *et al.*, 2000). (4) Activation of the afferent neurons, via the DRG, requires high-frequency stimulation of the sympathetic neurons at 5 to 20 Hz. Sympathetic pre- and postganglionic neurons rarely discharge at these frequencies under physiological conditions. (5) Mechanical allodynic and hyperalgesic behavior shown by rats with L5 spinal nerve injury (transection and ligation) is not dependent on the innervation of the DRG by sympathetic neurons (Ringkamp, M. *et al.*, 1999; see point 4 in Table 2). The rate of ectopic activity originating in

the DRG, 15 to 45 days after spinal nerve injury, is not maintained by activity in sympathetic neurons (Liu, X. *et al*., 2000). (6) Afferent neurons in the DRG may be activated indirectly by ischemia generated by decrease of blood flow during vasoconstriction in the DRG following electrical stimulation of the sympathetic trunk and not directly via adrenoceptors expressed in the DRG cells (Häbler, H.-J. *et al*., 2000). (7) Axotomized medium- to large-diameter DRG neurons express α_{2A}-adrenoceptors after sciatic nerve injury (Birder, L. A. and Perl, E. R., 1999). However, these upregulated adreceptors disappear after several weeks as perineural catecholaminergic sprouting develops and only small depolarizations can be generated by high concentrations of noradrenaline in axotomized DRG somata (Lopez de Armentia, M. *et al*., 2003).

The mechanism leading to the collateral sprouting of postganglionic noradrenergic fibers in the DRG is possibly related to neurotrophic signals and their receptors generated by afferent cells with lesioned axons in the DRG and the surrounding satellite glia cells (Chapter Sprouting in Dorsal Root Ganglia). Whether these aberrant pathological connections can account for spontaneous pain and allodynia in some patients after peripheral nerve lesions is doubtful and awaits further investigations (Jänig, W. *et al*., 1996).

5.17.3.3.4 Adrenoceptors involved in chemical sympathetic afferent coupling following nerve lesion

Excitation or depression of lesioned primary afferent neurons (in the DRG, in their lesioned terminals in the neuroma or in their regenerating sprouts), or of unlesioned collaterally sprouting primary afferents generated by activation of the sympathetic innervation, is mimicked by systemic injection of noradrenaline or adrenaline and prevented by blockade of α-adrenoceptors (e.g., phentolamine). Thus, both excitation and depression are suggested to be mediated by α-adrenoceptors. The cellular mechanisms underlying the increased sensitivity are unknown. Novel expression or upregulation of adrenoceptors occurs; alternatively, normally present adrenoreceptors that are not functional become uncovered and effective during the response to damage. The subtype of α-adrenoreceptor being involved in the sympathetic–afferent coupling in the different rat models is predominantly α_2 (Chen, Y. *et al*., 1996). Knowledge about the subtypes of adrenoceptor following nerve trauma may turn out to be useful in the design of more specific treatment modalities for neuropathic pain conditions involving sympathetic efferent activity (Jänig, W. *et al*., 1996; Jänig, W. and Häbler, H. J., 2000b).

5.17.3.3.5 Synopsis

Peripheral trauma with nerve injury may lead to sensitization and activation of nociceptive and activation of other primary afferent neurons. These processes may depend on and are maintained by the sympathetic nervous system. Several ways of coupling between sympathetic postganglionic neurons and primary afferent neurons are possible and have been worked out experimentally on animal models with controlled nerve lesions, showing that there may develop intimate relationships between sympathetic and afferent neurons under pathophysiological conditions (Figure 9):

1. The sympathetic postganglionic neuron may develop chemically mediated cross talk to primary afferent neurons. Whether this occurs probably depends on the time after nerve lesion as well as on the type of nerve lesion (partial or complete).
2. Following peripheral nerve lesion, remote collateral sprouting of unlesioned postganglionic fibers occurs in the DRG, preferentially toward the large-diameter sensory cells. Collateral sprouting of unlesioned postganglionic fibers may also occur in the peripheral target tissue (in particular after partial nerve lesion).
3. The transmission from sympathetic neurons to afferent neurons is mediated by noradrenaline, but additional mediator substances cannot be excluded.
4. Primary afferent neurons express functional adrenoceptors. The type of adrenoceptor involved is preferentially α_2 in animal models.
5. The signals that initiate the sprouting and the functional expression of adrenoceptors in the afferent neurons may be related to neurotrophic substances that derive from the Schwann cells or other cells. Their upregulation is related to the plastic changes of the primary afferent and sympathetic postganglionic neurons and possibly to decrease of the density of the noradrenergic innervation and/or to activity in the afferent and sympathetic neurons (see Chapter Sprouting in Dorsal Root Ganglia).

These plastic changes of primary afferent and sympathetic postganglionic neurons following peripheral trauma with nerve lesion may explain some of the

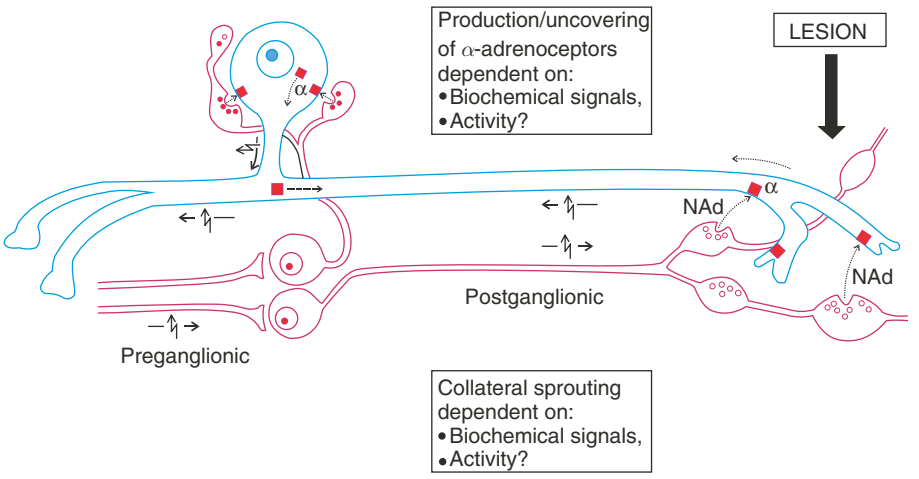

Figure 9 Relation between afferent and sympathetic neurons following peripheral nerve lesion. Collateral sprouting of unlesioned sympathetic neurons in the dorsal root ganglion (DRG) and in the peripheral target tissue. Upregulation or uncovering of functional adrenoceptors (α) by afferent neurons after nerve lesion. It is unclear in which way these processes are related to the biochemical signals (e.g., neurotrophins) synthesized by neurons, Schwann cells, and other cells in the DRG and the expression of their receptors. In which way are these processes dependent on activity in the afferent neurons, on the presence/absence of postganglionic noradrenergic neurons, or on the activity in the postganglionic neurons? NAd, noradrenaline. Modified from Jänig W. *et al.* (1996).

clinical sensory phenomena in patients with SMP, e.g., in CRPS type II. However, they do not explain (1) the slow development of spontaneous pain and allodynia after noradrenaline is injected into the skin that was painful before sympathetic block or before sympathectomy (Torebjörk, H. E. *et al.*, 1995) (Figure 4); (2) the long-lasting pain relief in patients with SMP after sympathetic blocks Figure 15 and (3) the mechanism of SMP in patients without nerve lesion, e.g., in patients with CRPS type I.

5.17.3.4 Indirect Involvement of the Sympathetic Nervous System in the Generation of Pain

Nociceptive afferents are embedded in a complex micromilieu (Figure 10). The state of this micromilieu surrounding the receptive terminals depends on mediator substances that are released during inflammatory processes following trauma from non-neural cells such as mast cells, polymorphonuclear leucocytes, macrophages, fibroblasts, endothelial cells, or other cells. The microcirculation is under neural control of sympathetic vasoconstrictor neurons. Moreover, activation of subgroups of nociceptive primary afferents causes not only orthodromic impulse traffic but also arteriolar (precapillary) vasodilation and (in most tissues, but not in human skin) venular plasma extravasation by release of neuropeptides from the receptive terminals (e.g., substance P (SP) and calcitonin-gene-related peptide (CGRP)). Both afferent-induced changes are called neurogenic inflammation (McDonald, D. M., 1997; Holzer, P., 1998). Thus, there are possibilities for indirect coupling between sympathetic and afferent nerve terminals (Figure 10): (1) Vascular perfusion of the micromilieu surrounding the nociceptors after nerve trauma may change as consequences of denervation and reinnervation by postganglionic vasoconstrictor neurons and afferent nociceptive neurons and hyper-reactivity of blood vessels to nerve impulses and circulating catecholamines may develop (Jobling, P. *et al.*, 1992; Koltzenburg, M. *et al.*, 1995). (2) Nociceptors may be sensitized by inflammatory mediators such as prostaglandins and interleukins, the release of which from nonneuronal cells of the micromilieu may be mediated by noradrenergic nerve terminals.

5.17.3.4.1 Changes of neurovascular transmission and development of hyperreactivity of blood vessels

Neural control of blood vessels can change dramatically after trauma with nerve lesion, but possibly also after trauma without (Koltzenburg, M. *et al.*, 1995):

1. Cutaneous blood vessels that are reinnervated after a nerve lesion exhibit stronger than normal

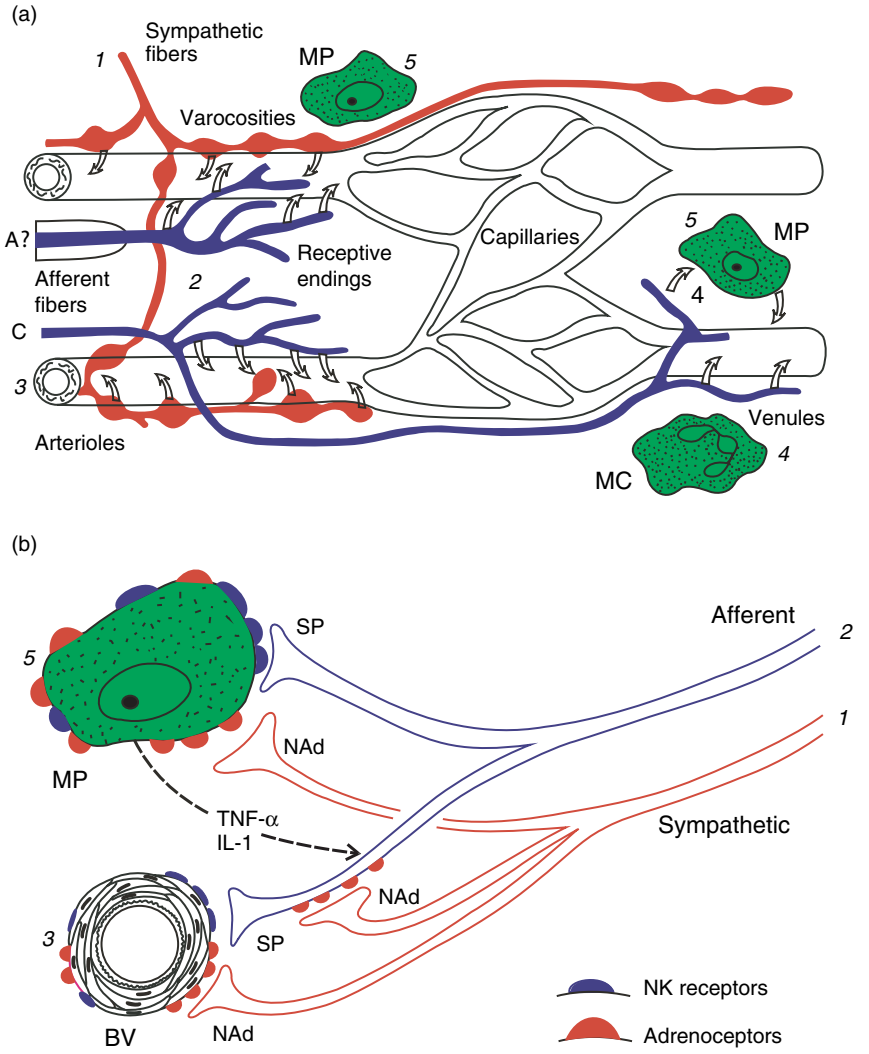

Figure 10 (a) The micromilieu of nociceptors. The microenvironment of primary afferents is thought to affect the properties of the receptive endings of myelinated (Aδ) and unmyelinated (C) afferent fibers. This has been particularly documented for inflammatory processes, but one may speculate that pathological changes in the direct surroundings of primary afferents may contribute to other pain states as well. The vascular bed consists of arterioles (directly innervated by sympathetic and afferent (Aδ, C) fibers), capillaries (not innervated and not influenced by nerve fibers), and venules (not directly innervated but influenced by nerve fibers). The micromilieu depends on several interacting components: Neural activity in postganglionic noradrenergic fibers (*1*) supplying blood vessels (*3*, BV) causes release of noradrenaline (NAd) and possibly other substances causing vasoconstriction. Excitation of primary afferents (Aδ- and C-fibers) (*2*) causes vasodilation in precapillary arterioles and plasma extravasation in postcapillary venules (C-fibers only) by the release of SP and other vasoactive compounds (e.g., calcitonin gene-related peptide, CGRP). Some of these effects may be mediated by nonneuronal cells such as mast cells (MC, *4*) and macrophages (MP, *5*). Other factors that affect the control of the microcirculation are the myogenic properties of arterioles (*3*) and more global environmental influences such as a change of the temperature and the metabolic state of the tissue (modified from Jänig, W. and Koltzenburg, M., 1991). (b) Hypothetical relation between sympathetic noradrenergic nerve fibers (*1*), peptidergic afferent nerve fibers (*2*), blood vessels (*3*, BV), and macrophages (*4*, MP). The activated and sensitized afferent nerve fibers activate macrophages (via SP release). The immune cells start to release cytokines, such as tumor necrosis factor α (TNF-α) and interleukin 1 (IL-1), which further activate afferent fibers by enhancing sodium influx into the cells. SP (and CGRP) released from the afferent nerve fibers reacts with neurokinin 1 (NK1) receptors (CGRP receptors) in the blood vessels (arteriolar vasodilation, venular plasma extravasation; neurogenic inflammation). The sympathetic nerve fibers interact with this system potentially on three levels: (1) via adrenoceptors (mainly α) on the blood vessels (vasoconstriction), (2) via adrenoceptors (mainly β) on macrophages (further release of cytokines), and (3) via adrenoceptors (mainly α) on afferents (further sensitization of these fibers). Modified from Jänig W. and Baron R. (2003).

vasoconstriction to impulses in sympathetic neurons.

2. The sympathetically reinnervated cutaneous blood vessels show stronger than normal vasoconstrictions to systemic catecholamines and appear to be hyper-reactive.
3. Blood vessels exhibit changes in vasodilation to antidromic activation of reinnervated peptidergic unmyelinated afferents.

The reinnervated blood vessels may therefore be under stronger than normal vasoconstrictor influence that can no longer be counteracted by an afferent-mediated vasodilation (see Häbler, H. J., *et al.*, 1997). *In vitro* investigation of the rat tail artery has shown that the functional recovery of neurovascular transmission is permanently disturbed after a nerve lesion (Jobling, P. *et al.*, 1992).

The altered neural and nonneural control of blood vessels, following trauma with nerve lesion, can contribute to the abnormal regulation of blood flow through skin and deep somatic tissues and possibly to the trophic changes (including the edema) that are seen in patients with CRPS. They may furthermore be a permissive factor in the generation of afferent nociceptive impulse activity and therefore in the sensitization of nociceptors and in the generation of pain.

Finally, it is commonly believed that skin temperature changes observed in painful disorders following trauma with or without nerve lesion (e.g., in CRPS I or II) reflect changes of activity in cutaneous vasoconstrictor neurons, in the sense that cold skin is associated with a high level and warm skin with a low level of activity in these neurons. This is probably a misconception, and there is no proof for this relation between skin temperature and activity in sympathetic neurons under these pathophysiological conditions.

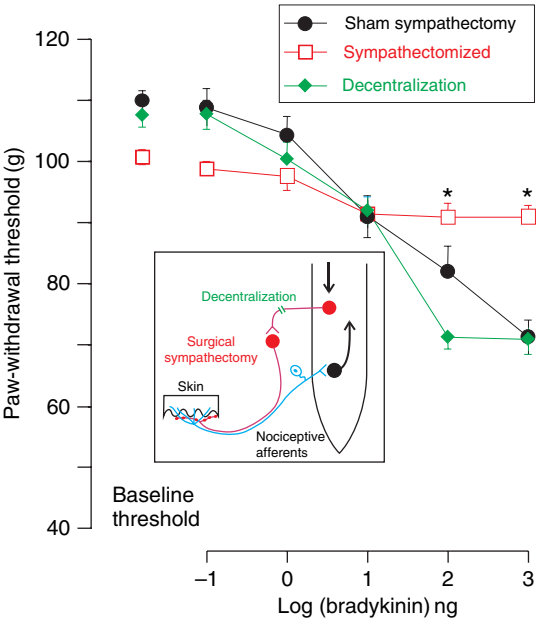

Figure 11 Mechanical hyperalgesic behavior and sympathetic innervation. Cutaneous nociceptors on the dorsum of the paw are stimulated by a linearly increasing mechanical force. Paw-withdrawal threshold (PWT) is defined as the mean (±SEM) minimum force (in grams, ordinate scale) at which the rat withdraws its paw. Abscissa scale: log dose of bradykinin (BK, in nanograms) injected in a volume of 2.5 µl of saline into the dermis of the skin. Decrease of PWT to mechanical stimulation induced by intradermal injection of BK in sham-sympathectomized (control) rats (●, 6 hindpaws), in surgically sympathectomized rats (lumbar paravertebral ganglia L2 – L4 removed 8 days before; □, 12 hindpaws), and in rats with decentralized lumbar sympathetic chains (white rami with preganglionic axons to paravertebral ganglia L2 and L3 and chain rostral to ganglion L2 transected 8 days before; ◆, 10 paws). Abscissa scale: log dose of BK (in nanograms). Sham sympathectomy and sympathetic decentralization were both significantly different from sympathectomy groups at doses of BK of 10^2 and 10^3 ng (*, $P < 0.01$). Modified from Khasar S. G. *et al.* (1998a).

5.17.3.4.2 Sensitization of nociceptors mediated by sympathetic terminals independent of excitation and release of noradrenaline

Withdrawal threshold to stimulation of the rat hindpaw with a linearly increasing mechanical stimulus applied to the dorsum of the paw decreases dose-dependently after intradermal injection of the inflammatory mediator bradykinin (an octapeptide cleaved from plasma α_2-globulins, by kallikreins circulating in the plasma) (Figure 11). Following a single injection of bradykinin, this decrease lasts for more than 1 h for mechanical stimulation. This type of mechanical hyperalgesic behavior is mediated by the B_2 bradykinin-receptor and is not present when bradykinin is injected subcutaneously (Khasar, S. G. *et al.*, 1993; 1995; Jänig, W. and Häbler, H. J., 2000b). In normal rat, bradykinin-induced hyperalgesic behavior is blocked by the cyclooxygenase inhibitor indomethacin and therefore mediated by a prostaglandin (probably PGE_2) that sensitizes nociceptors for mechanical stimulation. However, in vagotomized rats in which the bradykinin-induced

mechanical hyperalgesia is significantly enhanced (by activation of the adrenal medulla, see below and Figure 13a), indomethacin has almost no effect on bradykinin-induced hyperalgesia. This failure is not related to a switch from B2- to B1-receptor subtype because the selective B1-receptor agonist des-Arg9-bradykinin fails to produce hyperalgesia in vagotomized rats (Khasar, S. G. *et al.*, 1998a). The same applies to rats that were sound-stressed for 4 days (Khasar, S. G. *et al.*, 2005). Thus, bradykinin-induced hyperalgesia may not be mediated by prostanoids in vagotomized or sound-stressed rats. Furthermore, convincing sensitization to mechanical stimulation by bradykinin has only been demonstrated for afferent fibers innervating the cat knee joint (Neugebauer, V. *et al.*, 1989) or the cat skeletal muscle (Mense, S. and Meyer, H., 1988). Manning D. C. *et al.* (1991) demonstrated in humans that intradermal injection of bradykinin (100 ng to 10 µg) generates hyperalgesia to heat stimulation but not to mechanical stimulation.

The decrease in paw-withdrawal threshold to mechanical stimulation generated by intradermal injection of bradykinin is significantly reduced after surgical sympathectomy. Decentralization of the lumbar paravertebral sympathetic ganglia (denervating the postganglionic neurons by cutting the preganglionic sympathetic axons) does not abolish the bradykinin-induced mechanical hyperalgesic behavior (Figure 11). This indicates that the sensitizing effect of bradykinin is not dependent on activity in the sympathetic neurons innervating skin and therefore not on release of noradrenaline (Khasar, S. G. *et al.*, 1998a) and that bradykinin stimulates the release of prostaglandin from the sympathetic terminals or from other cells in association with the sympathetic terminals in the skin (Figure 6b).

Mechanical hyperalgesic behavior generated by intracutaneous injection of bradykinin and its dependence on the sympathetic innervation of the skin is an interesting phenomenon. However, that mechanical hyperalgesia is due to prostanoids sensitizing nociceptors since indomethacin prevents it appears to be too simple. The reasons are (1) the finding that sympathetic fibers mediate this hyperalgesia independent of neural activity and release of noradrenaline; (2) indomethacin does not block this behavior under certain conditions (e.g., when the adrenal medullae are activated after vagotomy (see below) or after sound stress); (3) sensitization of nociceptive afferents innervating deep somatic tissues by bradykinin to mechanical stimulation has been demonstrated in neurophysiological experiments in the cat, not yet in humans for cutaneous pain (Manning, D. C. *et al.*, 1991); (4) in skin there is a spatial dissociation between afferent nociceptive fibers and sympathetic fibers, many of the former ending in the epidermis and subepidermal plexus, whereas most of the latter terminate in deeper dermal layer, raising the question as to the nature of the interaction between both groups of fibers.

These points argue that the dependence of bradykinin-induced cutaneous mechanical behavior on the sympathetic innervation has to be reinvestigated using a rigorous experimental approach. Neurophysiological experiments are required to demonstrate that sensitization of nociceptors by bradykinin is dependent on the presence of sympathetic terminals.

5.17.3.4.3 Sensitization of nociceptors initiated by nerve growth factor or cytokines possibly mediated by sympathetic terminals

5.17.3.4.3.(i) Nerve growth factor Systemic injection of nerve growth factor (NGF) is followed by a transient thermal and mechanical hyperalgesia in rats (Lewin, G. R. *et al.*, 1993; 1994) and humans (Petty, B. G. *et al.*, 1994). During experimental inflammation (evoked by Freund's adjuvant in the rat hindpaw), NGF increases in the inflamed tissue paralleled by the development of thermal and mechanical hyperalgesia. Both are prevented by anti-NGF antibodies (Lewin, G. R. *et al.*, 1994). The mechanisms responsible are sensitization of nociceptors via high-affinity NGF-receptors (trkA receptors) and an increased synthesis of CGRP and SP in the afferent cell bodies induced by NGF taken up by the afferent terminals and transported to the cell bodies. The NGF-induced sensitization of nociceptors or part of it seems to be mediated indirectly by the sympathetic postganglionic terminals. In rats, heat and mechanical hyperalgesic behavior generated by local injection of NGF into the skin is prevented or significantly reduced after chemical or surgical sympathectomy (Woolf, C. J. *et al.*, 1996). These experiments suggest that the NGF released during inflammation by inflammatory cells acts on the sympathetic terminals via high-affinity trkA receptors, inducing the release of inflammatory mediators (the source of which is unknown) and subsequently sensitization of nociceptors for mechanical and heat stimuli (Figure 6c; McMahon, S. B., 1996; Woolf, C. J., 1996; Jänig, W. and Häbler, H. J., 2000b). It is unclear whether this sensitization of nociceptors mediated by terminal sympathetic nerve fibers (1) is dependent on activity

in the sympathetic neurons and release of noradrenaline and on adrenoceptors expressed in the nociceptive afferent neurons or (2) is independent of neural activity and release of noradrenaline.

5.17.3.4.3.(ii) Proinflammatory cytokines Based on behavioral experiments conducted on rats (studying mechanical and heat hyperalgesia), it has been shown that tissue injury, injection of the bacterial cell wall endotoxin lipopolysaccharide, or injection of carrageenan (a plant polysaccharide) stimulates tissue inflammation and leads to sensitization of nociceptors. Systematic pharmacological interventions using blockers or inhibitors of the various mediators demonstrate that the proinflammatory cytokines, tumor necrosis factor α (TNF-α), interleukin-1 (IL-1), IL-6, and IL-8 may be involved in this process of nociceptor sensitization and therefore in the generation of hyperalgesia (Woolf, C. J. *et al.*, 1996; 1997; Poole, S. *et al.*, 1999). Pathogenic stimuli lead to activation of resident cells and release of the inflammatory mediator bradykinin and other mediators. The inflammatory mediators and the pathogenic stimuli themselves activate macrophages, monocytes, and other immune-related cells that release TNF-alpha. Nociceptors are believed to be sensitized by two possible pathways (Figure 12): (1) TNF-α induces production of IL-6 and IL-1β by immune cells, whereby IL-6 enhances the production of IL-1β. These interleukins stimulate cyclooxygenase 2 (COX 2) and the production of prostaglandins (PGE_2, PGI_2) that in turn react with the nociceptive terminal via E-type prostaglandin receptors. (2) TNF-α induces the release of IL-8 from endothelial cells and macrophages. IL-8 reacts with the sympathetic terminals that are supposed to mediate sensitization of nociceptive afferent terminals by release of noradrenaline to act via β_2-adrenoceptors. These two peripheral pathways by which nociceptive afferents are hypothesized to be sensitized involving cytokines are under inhibitory control of circulating glucocorticoids (indicated by asterisks in Figure 12) and of other, anti-inflammatory, interleukins (e.g., IL-4 and IL-10 indicated by # in Figure 12).

It is important to emphasize that the mechanisms of sensitization of nociceptive afferents, involving NGF, proinflammatory cytokines, and noradrenergic sympathetic postganglionic fibers, have been deduced on the basis of behavioral and pharmacological experiments. Proof of such interaction by directly assessing the activity of nociceptors with electrophysiological techniques and of the effect of noradrenergic nerve fibers on the afferent nerve fibers are lacking. These experiments have to be done.

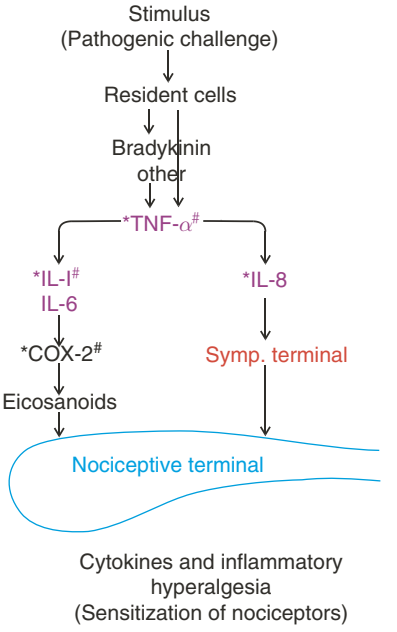

Figure 12 Hypothetical role of cytokines in sensitization of nociceptors during inflammation and the underlying putative peripheral mechanisms leading to hyperalgesia. Pathogenic stimuli activate resident cells and lead to release of inflammatory mediators (such as bradykinin). Proinflammatory cytokines are synthesized and released by macrophages and other immune or immune-related cells. Nociceptors are postulated to be sensitized by two pathways involving the cytokines: (1) Tumor necrosis factor α (TNF-α) induces synthesis and release of interleukin 1 (IL-1) and IL-6 which, in turn, induce the release of eicosanoids (prostaglandin E_2 and I_2 (PGE_2, PGI_2)) by activating cyclooxygenase-2 (COX-2). (2) TNF-α induces synthesis and release of IL-8. IL-8 activates sympathetic terminals that sensitize nociceptors via β_2-adrenoceptors. Glucocorticoids inhibit the synthesis of the cytokines and the activation of COX-2 (indicated by asterisks). Anti-inflammatory cytokines (such as IL-4 and IL-10) that are also synthesized and released by immune cells inhibit the synthesis and release of proinflammatory cytokines (indicated by #). This scheme is fully dependent on behavioral experiments and pharmacological interventions. The different steps will need to be verified experimentally using neurophysiological experiments. Modified from Poole S. *et al.* (1999).

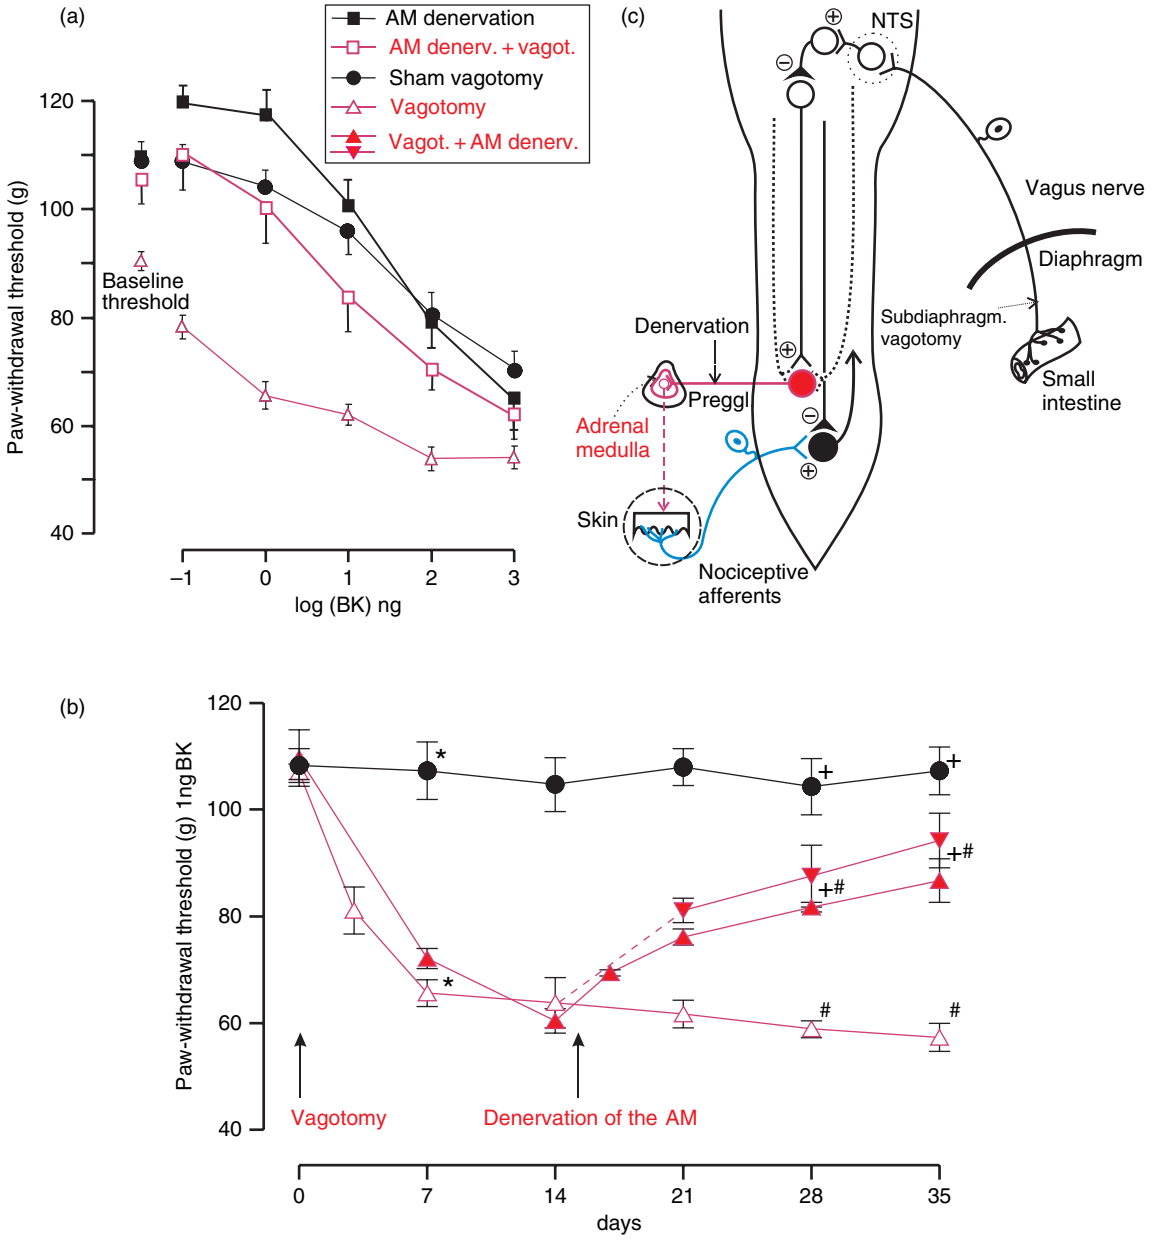
5.17.3.4.4 Sympatho-adrenal system and nociceptor sensitization

Activity of the sympatho-adrenal system (adrenal medulla) is regulated by central circuits that are different from those regulating other sympathetic systems (Morrison, S. F. and Cao, W. H., 2000;

Morrison, S. F., 2001; Jänig, W., 2006). Activation of this system (e.g., by release of the central sympathetic circuits, connected to preganglionic neurons that innervate the adrenal medulla, from vagal inhibition by subdiaphragmatic vagotomy (Figure 13c; Khasar, S. G. *et al.*, 1998a; 1998b), but not of the sympatho-neural system, generates mechanical hyperalgesia and enhances bradykinin-induced mechanical hyperalgesia (decrease of paw-withdrawal threshold to mechanical stimulation of the skin, compare closed circles with open triangles in Figure 13a). Both develop slowly over 7 to 14 days during continuous activation of the adrenal medullae (e.g., induced by subdiaphragmatic vagotomy) and are maintained over 5 weeks tested (open triangles in Figure 13b). In rats with denervated adrenal medullae (adrenal nerves with preganglionic axons innervating the cells of the adrenal medulla sectioned (Figure 13c)), subdiaphragmatic



vagotomy has only a small effect (compare open squares with closed squares in Figure 13a). This decrease of paw-withdrawal threshold can be explained by removal of inhibition of nociceptive impulse transmission in the spinal dorsal horn (Figure 13c; see Randich, A. and Gebhart, G. F., 1992; see Chapter Descending Control Mechanisms). Denervation of the adrenal medullae, 14 days after vagotomy when the decrease of paw-withdrawal threshold is maximal, is followed by a slow increase of paw-withdrawal threshold taking more than 3 weeks (compare closed triangles with open triangles in Figure 13b). Thus, the decrease of paw-withdrawal threshold following vagotomy is reversed after denervation of the adrenal medullae. Application of adrenaline through a minipump for 3 to 14 days slowly enhances the development of mechanical hyperalgesia induced by bradykinin injected intradermally. Furthermore, continuous application of a β_2-adrenoceptor blocker over 7–14 days by way of a minipump prevents the enhancement of this hyperalgesic behavior generated by activation of the adrenal medullae (Khasar, S. G. *et al.*, 2003).

The results of this experiment are interpreted in the following way: Adrenaline released by persistent activation of the adrenal medullae sensitizes cutaneous nociceptors for mechanical stimuli. This sensitization of nociceptors and its reversal are slow and take days to develop. The slow time course implies that the nociceptor sensitization cannot be acutely blocked by an adrenoceptor antagonist given intracutaneously or systemically. Adrenaline probably does not act directly on the cutaneous nociceptors but on cells in the microenvironment of the nociceptors inducing slow changes, which result in nociceptor sensitization. Candidate cells may be mast cells, macrophages, or keratinocytes, which then release substances that generate sensitization (Khasar, S. G. *et al.*, 1998b; Jänig, W. *et al.*, 2000; Jänig, W. and Häbler, H. J., 2000b). The change of sensitivity of a population of nociceptors generated by adrenaline released by the adrenal medullae that is regulated by the brain would be a novel mechanism of sensitization. This novel mechanism would be different from mechanisms that lead to activation and/or sensitization of nociceptors by sympathetic afferent coupling as discussed above (Figure 6d).

This peripheral mechanism of pain and hyperalgesia involving adrenaline released by the sympatho-adrenal system and acting on nociceptors may operate in ill-defined pain syndromes such as irritable bowel syndrome, functional dyspepsia, fibromyalgia, and chronic fatigue syndrome (Wolfe, F. *et al.*, 1990; Mayer, E. A. *et al.*, 1995; Clauw, D. J. and Chrousos, G. P., 1997). The conclusions about long-term sensitization of nociceptors for mechanical stimulation by adrenaline fully rest on behavioral experiments. Neurophysiological experiments *in vivo* on primary afferent nociceptive neurons are required to test directly whether all or only a subpopulation of nociceptors are sensitized.

Figure 13 Long-term enhancement of bradykinin (BK)-induced mechanical hyperalgesia after vagotomy and its disappearance after denervation of the adrenal medullae (AM). (a) Decrease of paw withdrawal threshold (PWT) to mechanical stimulation of the dorsum of the rat hindpaw induced by BK injected intradermally (BK-induced behavioral mechanical hyperalgesia), in sham-vagotomized rats (●, $n = 18$), in vagotomized rats (△, $n = 16$; 7 days after subdiaphragmatic vagotomy), in rats with denervated adrenal medullae (■, $n = 6$), and in vagotomized rats with denervated AM (□, $n = 6$). For details see legend of Figure 11. (b) Total change of PWT (baseline plus BK-induced) in response to intradermal injection of 1 ng BK in rats before and 7 to 35 days after vagotomy (△, $n = 6$), before and 7 to 35 days after sham vagotomy (●, $n = 8$) and in rats whose AM are denervated 14 days after vagotomy and measurements taken up to 35 days after initial surgery (▲, rats tested after vagotomy and denervation of the AM ($n = 6$); ▼, rats only tested after additional denervation of the AM ($n = 4$)). Note that 1ng BK injected intradermally does not significantly change the PWT in rats with intact vagus nerves (see (a)). $^{*}P < 0.01$, ▲/△ versus ● on day 7; $^{+}P > 0.05$ ▲/▼ versus ● on days 28 and 35; $^{\#}P < 0.01$, ▲/▼ versus △ on days 28 and 35. (c) Schematic diagram showing the proposed neural circuits in spinal cord and brainstem which modulate nociceptor sensitivity via the sympatho-adrenal system. Sensitivity of cutaneous nociceptors for mechanical stimulation is modulated by adrenaline released by the AM. Activation of the AM increases the sensitivity of the nociceptors. Activity in preganglionic neurons innervating the AM depends on activity in vagal afferents from the small intestine that has an inhibitory influence on the central pathways to these preganglionic (preggl) neurons. Thus, interruption of the vagal afferents leads to activation of the AM. It is hypothesized that these neuronal (reflex) circuits in the brainstem are under the control of upper brainstem, hypothalamus, and telencephalon. Dotted thin lines: Axons of sympathetic premotor neurons in the brainstem that project through the dorsolateral funiculi of the spinal cord to the preganglionic neurons of the AM. ⊕, excitation; ⊖, inhibition. Modified from Khasar S. G. *et al.* (1998b).

5.17.4 Sympathetic Nervous System and Central Integrative Mechanisms in the Control of Hyperalgesia and Inflammation

The brain is suggested to modulate inflammation via the sympatho-neural and/or the sympatho-adrenal system although the mechanisms underlying these influences are little understood. Any influence of this type will affect indirectly the sensitivity of nociceptors. Here I will briefly discuss the hypothetical role of both sympathetic systems: (1) in CRPS that is characterized by a peripheral inflammatory process (in addition to changes in the central nervous system) suggested to be dependent on the sympathetic nervous system; (2) in experimental inflammation (bradykinin-induced synovial plasma extravasation); and (3) in the potential modulation of the immune tissue.

5.17.4.1 The Complex Regional Pain Syndrome Type I as Model

CRPS are painful disorders that may develop as a consequence of trauma typically affecting the limbs. Clinically, they are characterized by pain (spontaneous, hyperalgesia, and allodynia), active and passive movement disorders including an increased physiological tremor, abnormal regulation of blood flow and sweating, edema of skin and subcutaneous tissues, and trophic changes of skin, appendages of skin, and subcutaneous tissues (Stanton-Hicks, M. *et al.*, 1995; Jänig, W. and Stanton-Hicks, M., 1996; Harden, R. N. *et al.*, 2001; Jänig, W. and Baron, R., 2002; 2003). CRPS type I (previously called reflex sympathetic dystrophy) usually develops after minor trauma with a small or no obvious nerve lesion at an extremity (e.g., bone fracture, sprains, bruises or skin lesions, and surgeries) and rarely also after remote trauma in the visceral domain or after a lesion of the central nervous system (e.g., stroke). An important feature of CRPS I is that the severity and combination of clinical symptoms are disproportionate to the severity and type of trauma with a tendency to spread in the affected distal limb. The symptoms are not confined to the innervation zone of an individual nerve. CRPS type II (previously called causalgia) develops after trauma with a mostly large nerve lesion (Stanton-Hicks, M. *et al.*, 1995; Jänig, W. and Stanton-Hicks, M., 1996; Harden, R. N. *et al.*, 2001).

On the basis of clinical observations and research on human patients and animals, the hypothesis has been put forward that CRPS (in particular type I) is a systemic disease involving the central and peripheral nervous system (Figure 14). Various traumas can trigger variable combinations of clinical phenomena in which the somatosensory system, the sympathetic nervous system, the somatomotor system, and peripheral (vascular and inflammatory) systems are involved (Harden, R. N. *et al.*, 2001; Jänig, W. and Baron, R., 2002; 2003). The central changes are reflected in changes of somatic sensations (increase of detection thresholds for mechanical, cold, warm, and heat stimuli), of motor performances, and of neural regulation of sympathetic effector systems (vasculature, sweat glands, inflammatory cells, etc.). Thus, it is hypothesized that the central representations of the sensory, motor, and sympathetic systems are changed. The peripheral changes consist of inflammation involving blood vessels, inflammatory cells, peptidergic afferent nerve fibers, and sympathetic afferent coupling (see above and Figures 6 and 10). The peripheral changes cannot be seen independently of the central ones; both interact with each other via afferent and efferent signals. Furthermore, the mechanisms that underlie CRPS cannot be reduced to one system or to one mechanism only (e.g., to sympathetic afferent coupling, to an adrenoceptor disease, to a peripheral inflammatory disease, and to a psychogenic disease) (Harden, R. N. *et al.*, 2001; Jänig, W. and Baron, R., 2002; 2003).

The centrally generated activity in sympathetic neurons may be involved in various ways in the pathogenesis of CRPS type I, the main argument being that the peripheral changes are reversed or aggravated after intervention at the peripheral sympathetic nervous system (sympathetic blocks, stimulation of the sympathetic innervation; Figure 14). Three points that are relevant in the present context of sympathetic nervous system, pain, and body protection need to be emphasized for CRPS type I with SMP:

- In a subgroup of CRPS I patients, pain or a component of pain is obviously dependent on activity in sympathetic neurons and related to activation or sensitization of nociceptors by noradrenaline released by the sympathetic fibers (SMP). The nociceptors have expressed adrenoceptors and/or the excitatory effect is generated indirectly, e.g., by way of changes in blood flow in deep somatic tissues of an extremity (Baron, R. *et al.*, 2002). Sympathetically

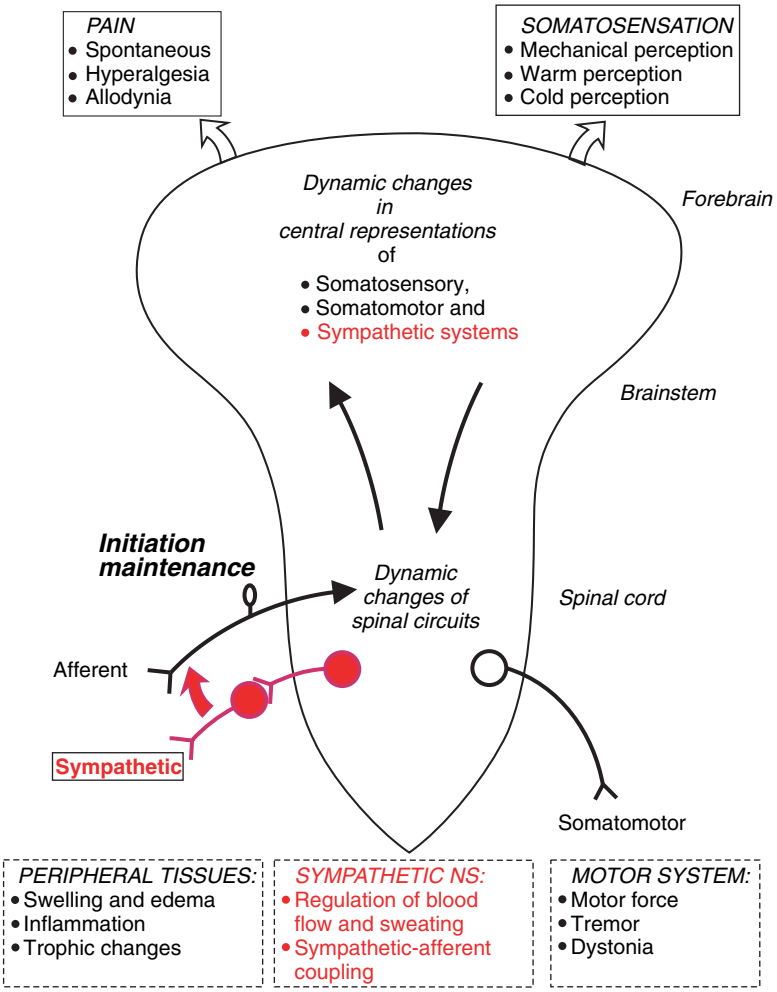


Figure 14 Schematic diagram summarizing the sensory, autonomic, and somatomotor changes in complex regional pain syndrome I (CRPS I) patients. The figure symbolizes the CNS (forebrain, brainstem, and spinal cord). Changes occur in the central representations of the somatosensory, the motor, and the sympathetic nervous system (which include the spinal circuits) and are reflected in the changes of the sensory painful and nonpainful perceptions, of cutaneous blood flow and sweating, and of motor performances. They are triggered and possibly maintained by the nociceptive afferent input from the somatic and visceral body domains. It is unclear whether these central changes are reversible in chronic CRPS I patients. These central changes affect the endogenous control system of nociceptive impulse transmission possibly too. Coupling between the sympathetic neurons and the afferent neurons in the periphery (see red arrow) is one component of the pain in CRPS I patients with sympathetically maintained pain (SMP). However, it seems to be unimportant in CRPS I patients without SMP. Modified from Jänig W. and Baron R. (2002; 2003).

maintained activity in nociceptive neurons may generate a state of central sensitization/hyperexcitability that is responsible for spontaneous pain and secondary evoked pain (mechanical and cold allodynia; see above and Figures 5 and 7).

- Swelling (edema) and inflammation may be generated by sympathetic and peptidergic afferent fibers interacting with each other at the arteriolar site (influencing blood flow) and venular site (influencing plasma extravasation) of the vascular bed. Sympathetic fibers are suggested to influence inflammatory cells (macrophages and mast cells) by way of noradrenaline and adrenoceptors on the inflammatory cells (Figure 10) (Jänig, W. and Baron, R., 2002; 2003).
- Trophic changes in skin, appendages of skin, and subcutaneous tissues (including joints and so forth) are believed to be dependent, at least in part, on the sympathetic innervation. The nature of this neural influence on the tissue structure is unknown (Jänig, W. and Stanton-Hicks, M., 1996; Harden, R. N. *et al.*, 2001; Jänig, W. and Baron, R., 2003).

These three groups of observation made on patients with CRPS I (who have no nerve lesion and therefore by definition not neuropathic pain) argue that the change of activity in sympathetic neurons entails peripheral changes which in turn may result in secondary activation and/or sensitization of primary afferent nociceptive neurons. The underlying mechanism(s) of this activation/sensitization of nociceptive afferent neurons may involve short- and long-term processes as discussed above

As already mentioned above, an important observation, in CRPS I patients with SMP (but possibly also in CRPS II patients with SMP), is that pain relief following conduction block of sympathetic neurons by a local anesthetic applied to the sympathetic chain mostly outlasts the conduction block by at least an order of magnitude (days) (Figure 15; Price, D. D. *et al.*, 1998). The long-lasting pain-relieving effect of sympathetic blocks suggests that activity in sympathetic neurons, which is of central origin, maintains a positive feedback circuit via the primary afferent neurons that are probably nociceptive in function. This positive feedback circuit maintains a central state of hyperexcitability (e.g., of neurons in the spinal dorsal horn; Figure 7), via excitation of afferent neurons started by an intense noxious event. The persistent afferent activity needed to maintain such a state of central hyperexcitability is switched off during temporary block of conduction in the sympathetic chain lasting only a few hours and cannot be immediately switched on again when the conduction block wears off and the activity in the sympathetic postganglionic neurons (and therefore probably also the sympathetically induced activity in afferent neurons) returns. It is hypothesized that the afferent activity has to act over a long time period to initiate and maintain the central state of hyperexcitability (via the positive feedback). The mechanism underlying this important and interesting phenomenon needs to be studied experimentally in patients with SMP as well as in animal models that have to be designed.

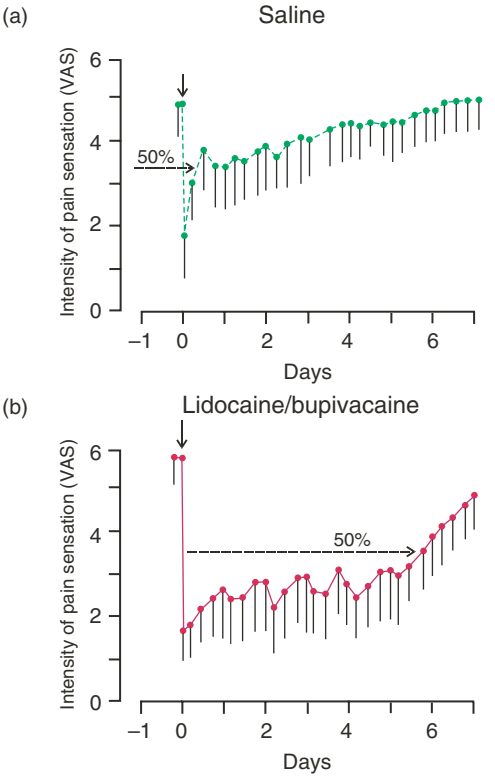

Figure 15 Effect of sympathetic blocks with a local anesthetic (lidocaine/bupivacaine) or of injection of saline close to the corresponding paravertebral sympathetic ganglia on pain in seven patients with CRPS I. Double-blind crossover study. Effect on pain following both interventions at the sympathetic supply was measured in the same group of CRPS I patients. Pain was systematically measured repeatedly using the visual analogue scale (VAS) on the day of the injection and on 7 days after the injection. Both interventions produced pain relief (see 50% value of pain relief). However, the mean relief of pain to injection of the local anesthetic lasted for 6 days and was significantly longer than the mean pain relief following local injection of saline that lasted for 6 h (placebo block). The initial maximal peaks of analgesia were statistically not different. Means + SEM. Modified from Price D. D. *et al.* (1998).

5.17.4.2 Sympathetic Nervous System and Acute Experimental Inflammation

Inflammation of body tissues is accompanied by sensitization of nociceptors leading to ongoing pain and hyperalgesia (Figure 7). The sensitization of nociceptors is generated by various signaling molecules released by the inflammatory cells including cells of the immune system (Figures 10 and 12; McMahon, S. B. *et al.*, 2006; Meyer, R. A. *et al.*, 2005). Inflammation is potentially controlled by the brain via the HPA system, the sympatho-neural system, and the sympatho-adrenal system (Figure 16c), resulting in an enhancement or inhibition of the inflammatory (protective) responses depending on the behavioral state of the organism. Any change in neural and neuroendocrine control of inflammation should indirectly affect the sensitization of nociceptors innervating the inflamed tissue and therefore ongoing pain and hyperalgesia. Although we know relatively little about the role of both sympathetic systems in the

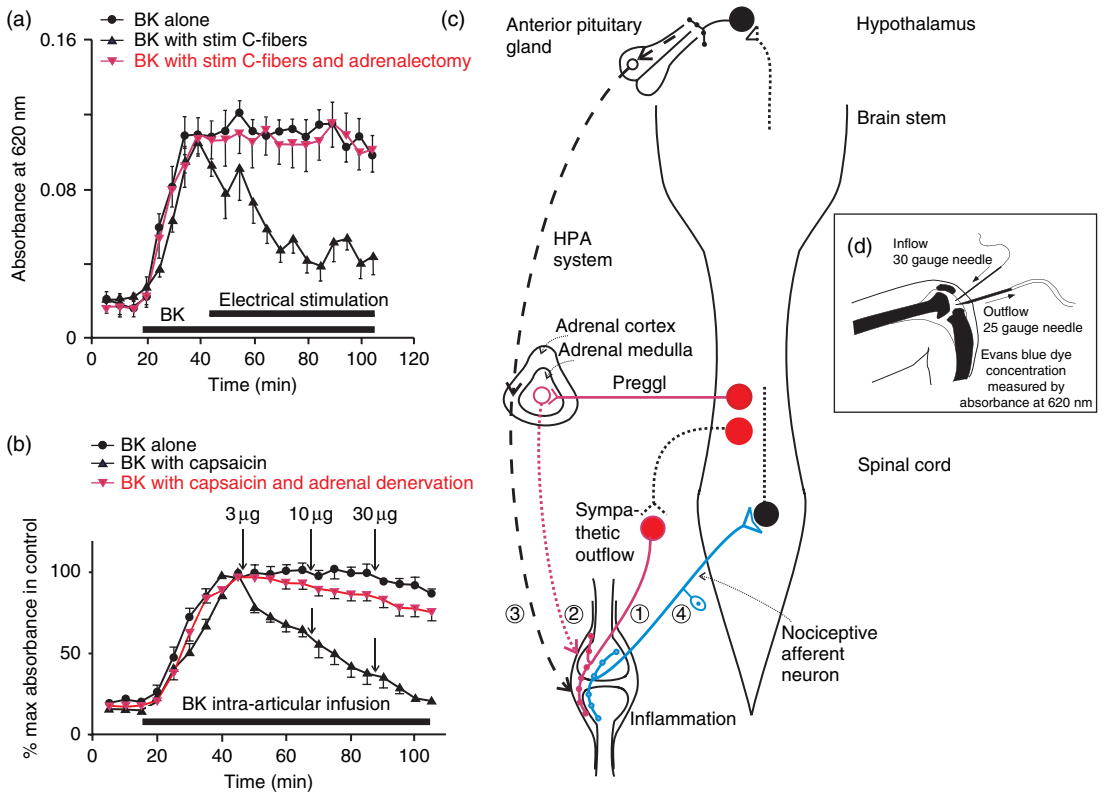

Figure 16 Experimental inflammation is controlled by the hypothalamo-pituitary system and the sympatho-adrenal system. Bradykinin (BK)-induced plasma extravasation (PE) was determined in the knee joint of anesthetized rats (d). Skin overlying the knee was excised to expose the joint capsule, and rats were then given an intravenous injection of Evans blue dye (50 mg kg $^{-1}$). The 30-gauge inflow and 25-gauge outflow needles were then inserted into the knee joint cavity for the inflow of perfusion fluid (0.9% saline at 250 µl min^{-1}). Perfusion fluid was collected over 5-min periods for up to 120 min and dye concentration determined spectrophotometrically at 620 nm. The absorbance at this wavelength is linearly related to the dye concentration and therefore to the degree of PE of the synovia (see ordinate scales in (a) and (b)). Following collection of the first three samples to establish baseline PE levels when the joint cavity is perfused with saline, BK (160 nM; and other substances) is (are) added to the perfusing fluid. This produces a rapid and sustained increase in the magnitude of PE (● in (a) ($n = 8$) and (b) ($n = 16$)). (a) Noxious transcutaneous electrical stimulation (25 mA, 3 Hz, 0.25 ms pulses) exciting C-fibers applied to the contralateral hindpaw after sample 8 produces a rapid decrease in the magnitude of PE (▲, $n = 7$). This inhibition produced by noxious electrical stimulation is prevented in rats in which the adrenal gland had been removed 1 week prior to the perfusion study (▼, $n = 7$). (b) Stimulation of cutaneous nociceptors by capsaicin injected into the palmar skin of the rat forepaw (3, 10, 30 µg in 2.5 µl) decreased the magnitude of PE (▲, $n = 8$). This inhibition produced by capsaicin was prevented in rats with denervated adrenal medullae (section of the adrenal nerves; ▼, $n = 8$). The rats were vagotomized. (c) Schematic diagram showing the neural and neuroendocrine components being involved in the control of BK-induced synovial PE: (*1*) Terminals of sympathetic postganglionic neurons mediate 60–70% of BK-induced synovial PE and the inhibitory effect of corticosterone on BK-induced synovial PE. (*2*, *3*) Control of BK-induced PE by the HPA system and the sympatho-adrenal system. (*4*) Change of sensitivity of nociceptive afferents during inflammation as well as modulation of experimental inflammation by peptides released these afferents. The central nociceptive–neuroendocrine reflex circuits are not shown (see Green, P. G. *et al.*, 1995; Miao, F. J.-P. *et al.*, 2000; 2001). Mean + SEM in (a) and (b). (a) after Green P. G. *et al.* (1995); (b) after Miao F. J.-P. *et al.* (2000); (d) after Jänig W. *et al.* (2006).

control of inflammation (see Straub, R. H. *et al.*, 2005; Straub, R. H. and Härle, P., 2005), I will summarize the role of both systems in the control of acute experimental inflammation generated in the rat knee joint perfused with the inflammatory mediator bradykinin (bradykinin-induced plasma extravasation).

Continuous perfusion of bradykinin through the rat knee joint (Figure 16d) produces a large, sustained increase in plasma extravasation with a decay of about 10% over 1–2 h (Figure 16a and b, filled circles). This bradykinin-induced plasma extravasation response is largely dependent on the postganglionic

sympathetic neuron terminal: surgical sympathectomy reduces the magnitude of response by 60–70%, but acute sympathetic decentralization (section of the preganglionic axons) has no significant effect. Similarly, acute interruption of the lumbar sympathetic chains during ongoing bradykinin-induced plasma extravasation does not reduce this extravasation. Finally, the sodium channel blocker tetrodotoxin coperfused with bradykinin into the knee joint cavity does not reduce the plasma extravasation (Miao, F. J.-P. *et al.*, 1996a; 1996b). Thus, bradykinin-induced synovial plasma extravasation is dependent on the presence of sympathetic terminals in the synovia, but not on activity in these terminals and not on release of noradrenaline (function *1* in Figure 16c). This dependence on the sympathetic terminals is particularly large at bradykinin concentrations that have been measured in inflamed tissues (10^{-8} to 10^{-7} M; Hargreaves, K. M. *et al.*, 1993; Swift, J. Q. *et al.*, 1993). This is a novel peripheral function of postganglionic sympathetic fibers, at least in the context of the model of synovial inflammation, produced by the potent endogenous inflammatory mediator bradykinin. This function occurs at the postcapillary venules by release of a chemical substance (possibly prostaglandin E2 and/or related substances), which is independent of the electrical activity in the sympathetic neurons. Whether this substance is released by the sympathetic terminals or by other cells in association with these terminals is unknown. Future investigations will have to show whether this unusual function of sympathetic postganglionic terminals also applies to other inflammatory models.

Bradykinin-induced synovial plasma extravasation is under control of the brain mediated by the sympatho-adrenal system and the HPA system (functions *2* and *3* in Figure 16c). Both the neuroendocrine control systems can be reflex activated by noxious stimuli. The HPA system is most efficiently activated by continuous transcutaneous electrical stimulation of afferent C-fibers and the sympatho-adrenal system during stimulation of nociceptors by capsaicin (e.g., injected into the plantar or palmar skin or into the peritoneal cavity).

The differential activation of both neuroendocrine systems, the hypothalamic–pituitary system and the sympatho-adrenal system, generated by the modes of afferent stimulation is interesting but puzzling. During transcutaneous electrical stimulation, C-fibers are stimulated continuously and synchronously at 1–4 Hz together with A-fibers. This activation of C-fibers is certainly unphysiological. Capsaicin injected into the skin or into the peritoneal cavity excites only C-fibers (and a few Aδ-fibers; but not Aβ-fibers) asynchronously. This activation is similar to physiological activation, e.g., by heat. These modes of afferent stimulation can be used to differentially activate both neuroendocrine systems experimentally whatever the central underlying mechanisms are for this differential activation.) The nociceptive–neuroendocrine reflex circuits in spinal cord and brainstem are enhanced after subdiaphragmatic vagotomy; thus, they are under inhibitory control of central circuits activated by abdominal vagal afferents. Both the central nociceptive–neuroendocrine reflex circuits and their inhibitory control exerted by activity in abdominal vagal afferents are described elsewhere (Miao, F. J.-P. *et al.*, 1997a; 1997b; 2000; 2001; 2003).

Transcutaneous electrical stimulation of C-fibers inhibits bradykinin-induced plasma extravasation (normal triangles in Figure 16a). This inhibition is mediated by the HPA system since it can be prevented by removal of the adrenal glands (inverted triangles in Figure 16a), by hypophysectomy, by blockade of the corticosterone metabolism, and by blockade of corticosterone receptors. It can be mimicked by intravenous infusion of corticosterone (Green, P. G. *et al.*, 1997). The inhibition of bradykinin-induced plasma extravasation generated by activation of the HPA system or by intravenous infusion of corticosterone is dependent on the presence of sympathetic postganglionic nerve fibers in the synovia: The bradykinin-induced plasma extravasation remaining after sympathectomy (removal of paravertebral ganglia) cannot any longer be inhibited by activation of the hypothalamic–pituitary system or by corticosterone injected intravenously. This shows that the sympathetic fibers are in a strategic, yet unexpected, position in the control of synovial plasma extravasation by the brain (Green, P. G. *et al.*, 1997).

Reflex inhibition of bradykinin-induced plasma extravasation generated by stimulation of nociceptors by capsaicin (normal triangles in Figure 16b) is prevented by denervation of the adrenal medullae (inverted triangles in Figure 16b). Thus, it is mediated by adrenaline released by the adrenal medullae.

The mechanisms by which corticosterone released by the adrenal cortex and adrenaline released by the adrenal medulla depress bradykinin-induced synovial plasma extravasation and the role of the sympathetic nerve fibers innervating the synovia in this depression are unknown. Corticosterone seems to act via the peptide annexin possibly released by inflammatory cells in

the synovia (Green, P. G. *et al.*, 1998). Here it is important to emphasize that the control of experimental synovial inflammation by both neuroendocrine systems affects indirectly the sensitivity of nociceptors innervating the knee joint and, therefore, also pain and hyperalgesia and that this change of sensitivity is therefore under the control of the brain.

5.17.4.3 Sympathetic Nervous System and Immune System

The hypothalamus can influence the immune system by way of the sympathetic nervous system and can therefore control protective mechanisms of the body at the cellular level (Besedovsky, H. O. and del Rey, A., 1995; Hori, T. *et al.*, 1995; Madden, K. S. and Felten, D. L., 1995; Madden, K. S. *et al.*, 1995). The parameters of the immune tissues potentially controlled are proliferation, trafficking and circulation of lymphocytes, functional activity of lymphoid cells (e.g., activity of natural killer cells) and cytokine production, hematopoesis of bone marrow, mucosal immunity, thymocyte development, etc. (for details of potential mechanisms, see Elenkov, I. J. *et al.*, 2000). The mechanisms of this influence remain largely unsolved (Ader, A. and Cohen, N., 1993; Saphier, D., 1993; Besedovsky, H. O. and del Rey, A., 1995). It is unknown (1) whether there exists a functionally distinct sympathetic system from the brain to the immune system or (2) whether the modulation of the immune system is a general function of the sympathetic nervous system. The more likely hypothesis favored by me is that the immune system is modulated by the brain by way of a functionally and anatomically distinct sympathetic pathway (Figure 17; for discussion, see Jänig, W. and Häbler, H. J., 2000a; Jänig, W., 2006). The reflex discharge characteristics of the neurons of this hypothetical sympathetic pathway innervating the immune tissue and the neural circuits in spinal cord, brainstem, and hypothalamus being involved in regulation of the activity of this pathway should be different from those of other sympathetic pathways (Jänig, W., 2006). In fact a hypothalamo-sympathetic neural system that controls the immune system has been postulated (Hori, T. *et al.*, 1995). In both cases it is hypothesized that activity in the sympathetic neurons supplying the immune system entails indirect modulation of the sensitivity of nociceptors involving various types of immune-related cells and their signaling molecules (e.g., cytokines, see above and Jänig, W. and Levine, J. D., 2006).

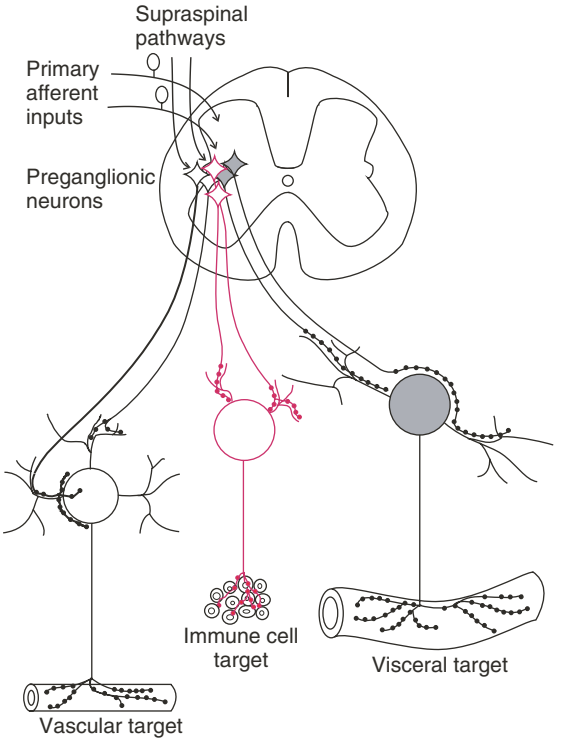

Figure 17 A separate sympathetic pathway to the immune tissue: a hypothesis. Demonstrated are three functional types of sympathetic pathway, one each to the vasculature (e.g., to blood vessels in skeletal muscle or skin or viscera), to the viscera (e.g., to the gastrointestinal tract being involved in the regulation of motility or secretion), or to the immune tissue. This neural link to the immune tissue may indirectly lead to sensitization of nociceptors and pain (modified from Jänig, W., 2006).

5.18.1 Introduction

Traditionally, the sympathetic nervous system (SNS) is considered as an efferent system that controls peripheral blood flow, sweating, and piloerection. This autonomic part of the nervous system, however, may play a pivotal role in certain pain conditions. Over the last decade, much knowledge has been gained on the mechanisms of interaction between the sensory afferent and sympathetic efferent systems. Pain dependent on the discharge of sympathetic nerves is referred to as sympathetically maintained pain (SMP). Insights into the pathophysiology of SMP help its treatment. The concept of SMP stemmed from clinical observations that certain patients with persistent pain after traumatic nerve lesions received dramatic pain relief from blockade of sympathetic ganglion with local anesthetic agents or perivascular sympathectomy.

A pain syndrome often associated with SMP is now termed complex regional pain syndrome (CRPS). Only subsets of patients with CRPS have SMP. Formerly termed as reflex sympathetic dystrophy (RSD), CRPS is an incompletely understood pain disorder that usually results from a traumatic injury and clinically presents as nondermatomal distribution of pain and sensory abnormalities in an extremity. Symptoms and signs include hyperalgesia and allodynia (enhanced pain to natural stimuli such as a pin prick or light stroking of the skin, respectively), autonomic features, and motor dysfunction. Some patients in addition have a motor impairment not readily explained by a lesion in the peripheral nervous system. Edema at the time of presentation or at an earlier time point is a common feature. CRPS may be present in cases with (CRPS type II) or without a nerve lesion (CRPS type I). After the initial description of this disease by Weir Mitchell in 1864 (who called it causalgia) and decades later by Paul Sudeck (Sudeck's syndrome), Leriche advocated its treatment by sympathetic interruption in 1916. Leriche (vicious cycle hypothesis, 1939) and Mandl (1947) were pioneers in proposing the connection between pain and SNS. The concept that the SNS was involved in the mechanisms of pain in CRPS was further propagated by Evans, who coined the term reflex sympathetic dystrophy. In view of the explosion of research regarding mechanisms of pain in RSD and lack of uniform diagnostic criteria, major taxonomical changes were proposed by the International Association for the Study of Pain (IASP) Consensus Team, and the term complex regional pain syndrome was introduced (Stanton-Hicks, M. *et al.*, 1995). According to the IASP classification, two distinct subtypes are now identified. Patients in whom the above-described

conglomeration of symptoms and signs develop after injury to a major peripheral nerve are considered to have CRPS type II (previously known as causalgia). The remaining patients in whom injuries to a limb or lesions in remote body areas precede the onset of symptoms without any identifiable nerve damage are classified as CRPS type I (previously termed reflex sympathetic dystrophy) (Merskey, H. and Bogduk, N., 1995). Since the initial proposal of diagnostic criteria for CRPS, further modifications have been made (Harden, R. N. and Bruehl, S. P., 2006). Presently, the clinical signs and symptoms of CRPS are grouped into the following categories:

1. Positive sensory abnormalities (spontaneous pain, mechanical, somatic or deep somatic hyperalgesia).
2. Vascular abnormalities (vasodilation or vasoconstriction, skin temperature asymmetries, or skin color changes).
3. Sudomotor abnormalities (swelling, hyper-, or hyperhidrosis).
4. Motor changes (weakness, tremor, dystonia, or coordination deficits) and trophic changes (nail or hair changes, skin atrophy, joint stiffness, or soft-tissue changes).

The criteria are being further validated as no gold standard diagnostic tool has been established for CRPS (Baron, R. and Jänig, W., 2004; Harden, R. N. and Bruehl, S. P., 2006). The 1993 IASP consensus team also acknowledged the term sympathetically maintained pain (SMP) and defined it as "Pain that is maintained by sympathetic efferent innervation or by circulating catecholamines." A role for circulating catecholamines has not been clearly established though. SMP is traditionally diagnosed by relief of allodynia, hyperalgesia, ongoing pain, and a selective blockade of sympathetic function. Notably, patients with CRPS, as previously indicated, may have both SMP and sympathetically independent pain (SIP) in varying proportions (Stanton-Hicks, M. *et al.*, 1995).

Even after decades of animal and human research, the pathophysiology of CRPS remains uncertain. Though it is common to refer to CRPS as a neuropathic pain disorder, it is not clear that pathology of the nervous system is at the root of this disorder as patients with or without nervous system lesions may manifest with symptoms of CRPS (Jänig, W. and Baron, R., 2002; 2003; 2004). Moreover, it is clear that CRPS is a diagnosis of exclusion, as other diseases (e.g., nerve entrapment and diabetic neuropathy) may present with similar signs and symptoms.

5.18.1.1 Sympathetically Maintained Pain

The clinical picture of CRPS with vascular (vasodilation or vasoconstriction, skin temperature asymmetries, or skin color changes) and sudomotor abnormalities (swelling, hyper-, or hypohidrosis) perhaps promoted the initial idea of SNS dysfunction as the primary etiology of the disease. Several lines of evidence suggest a dysregulation of autonomic function in the initial phase of the disease. Furthermore, enhancement of spontaneous pain and hyperalgesia after physiological activation of SNS (Baron, R. *et al.*, 2002; Drummond, P. D. and Finch, P. M., 2004) and resolution of pain, physiological tremor, and swelling in some patients after sympathetic blocks strengthen this view. The detection of autoantibodies against the autonomic nervous system in certain CRPS patients provides further evidence to this concept.

The relief of pain by blockade of the SNS initially invited speculation of an increased SNS discharge as a potential mechanism for SMP. Several observations were against this hypothesis. First, patients with SMP, particularly in the early period of the disease, may present with warm rather than cold skin. Under conditions of increased sympathetic discharge, vasoconstriction should lead to a cold skin. Also others noted that catecholamine levels in the venous return of the affected extremity were below those in normal subjects or their unaffected side.

In 1948, Walker *et al.* made an important clinical observation that provided convincing evidence for SMP. At that time, sympathectomy was performed to treat limb ischemia and also to relieve pain in patients with causalgia. Walker and colleagues performed a preganglionic sympathectomy and placed electrodes on the ganglion. Postoperatively, the ganglion was stimulated. Since the ganglion was dissociated from the spinal cord, electrical stimulation would only induce an efferent discharge in the peripheral sympathetic fibers. Stimulation induced pain in patients with causalgia, but not in patients with limb ischemia. This indicated that SMP was due to efferent function of the SNS. In a further experiment performed decades later, norepinephrine was injected in patients with SMP. In these patients, the sympathetic ganglia were blocked with local anesthetic. If SNS dysfunction does exist, does it involve under- or overactivity? Earlier description of the disease promoted the concept of distinct phases with an initial phase involving warm, erythematous skin (stage I or acute stage) presumably due to SNS underactivity, an intermittent phase of both warm and cold sensation

(stage II or dystrophic stage) followed by chronic cold sensation (stage III or atrophic stage) due to SNS hyperactivity. Although the existence of distinct phases of CRPS is debated at present (Bruehl, S. *et al.*, 2002), many studies have shown that vasomotor tone is reduced in very early stages of CRPS (Kurvers, H. A. *et al.*, 1995; Wasner, G. *et al.*, 2001), but not in later stages. The finding of reduced plasma norepinephrine and neuropeptide Y concentration on the affected extremity in early phase of the disease confirms this proposition (Raja, S. N. *et al.*, 1995). It seems that the apparent increase in vasomotor tone in later stages of CRPS (as evident by vasoconstriction or cold skin) is due to increased sensitivity (hyper- or supersensitivity) of skin microvessels to catecholamines (Kurvers, H. A. *et al.*, 1995) or secondary changes in neurovascular transmission while actual sympathetic tone is still depressed. Possible mechanisms for this supersensitivity might be decreased neuronal uptake of norepinephrine in the sympathetic neuroeffector junction (Raja, S. N. *et al.*, 1995) or increased number of peripheral α-receptors (Davis, K. D. *et al.*, 1991; Ali, Z. *et al.*, 2000). Studies in experimental animals report an increased expression of α-adrenoceptors in the neuromas that develop after nerve damage. Norepinephrine causes increased excitation of the neuroma afferents. Peripheral nerve injury may also result in sprouting of adrenergic fibers into the dorsal root ganglion and forms contact with sensory neurons. Thus, sympathetic afferent interactions might exist in the vicinity of the sensory receptors in partially denervated peripheral tissues, the peripheral nerve at the site of injury, and the dorsal root ganglion where cell bodies of injured sensory nerves are located.

Although SNS dysfunction is a fascinating concept, it does not explain all features of CRPS. Inflammatory and central origin of pain in CRPS patients has been suggested, and significant animal and human research support their contributions. The readers are advised to review the articles by Jänig W. and Baron R. (2003; 2004) for further understanding in this matter. Readers are also encouraged to read the conflicting views of Ochoa J. and Verdugo R. J. (2001) on the existence of SMP as well as the value of diagnostic phentolamine test or sympathetic blocks. The authors have negated the existence of SMP based on their own studies (Verdugo, R. J. and Ochoa, J. L., 1994), which in our opinion, had methodological deficiencies. A detailed discussion of these mechanisms and opposing views is beyond the scope of this chapter.

5.18.2 Techniques of Sympathetic Blockade

The techniques to achieve sympathetic blockade include the following:

1. Local anesthetic regional block (LASB) of sympathetic ganglion or trunk, for example, stellate ganglion block or lumbar sympathetic block.
2. Neuraxial techniques, for example, epidural or spinal block.
3. Intravenous regional sympathetic blockade (IRSB) with phentolamine, guanethidine, bretylium, clonidine, or lidocaine using tourniquet (Bier block technique).
4. Intravenous infusion of systemic alpha-adrenergic antagonists.
5. Radiofrequency denervation of sympathetic ganglion or trunk.
6. Surgical sympathectomy.

While LASB, IRSB with sympatholytic or local anesthetic medications, neuraxial techniques, and intravenous infusion of adrenergic antagonist can be used for both diagnostic and therapeutic benefits, neurolytic procedures (e.g., 5 and 6) are reserved for treatment of selected patients who show consistent but short-lasting response to initial diagnostic modalities.

5.18.3 Sympathetic Block for Diagnosis

The effectiveness of any diagnostic test or procedure is measured by its sensitivity and specificity. A good diagnostic test, when performed appropriately, should give consistent results in a given patient and should help guide therapy or predict outcome. Before any meaningful conclusions can be drawn from a sympathetic block by any technique, optimum inhibition of sympathetic outflow to the involved extremity needs to be achieved. This requires knowledge of the anatomical distribution of sympathetic innervation and the common pitfalls associated with the conduct and interpretation of these procedures. For instance, in performing stellate ganglion block to achieve an upper extremity sympathetic blockade, it is imperative to block contributions from upper thoracic ganglions that are anatomically separate from the stellate ganglion. This could be achieved by modifications in the previous technique. Similarly, injection of local anesthetic solution into nearby

vascular structures could cause failure to achieve sympatholysis. This can be avoided with the use of intravenous contrast agent and live fluoroscopy to rule out intravascular placement of needle tip.

Following sympathetic blockade, determination of adequacy of sympatholysis is imperative. Monitoring skin temperature change is commonly used in clinical practice. Adequate sympathetic blockade is inferred by approximation of core body temperature and skin temperature of the ipsilateral limb. Accepting a rise in skin temperature by an arbitrary number in comparison with the contralateral limb leads to higher false-positive blocks (Schurmann, M. *et al.*, 2001), probably due to bilateral increase in blood flow following sympathetic block techniques. Many authors recommend further assessment of sympathetic function by sweat test (Stevens, R. A. *et al.*, 1998) or skin conductance response.

5.18.3.1 Local Anesthetic Sympathetic Blocks

LASBs are technically challenging procedures that require training. They have the advantage of selectively blocking stellate or lumbar sympathetic ganglion and/or chain with a small dose of local anesthetic solution without concomitant blockade of sensory or motor fibers (Table 1). Using fluoroscopic or CT guidance, the needle tip is positioned in close proximity to the sympathetic ganglia and a local anesthetic solution is injected. Although numerous complications of LASB have been reported in the literature, these techniques are safe in experienced hands. Efficacy of the block is assessed as previously described by monitoring objective evidence of sympathetic blockade, for example, cutaneous temperature monitoring. The patient is asked to report the intensity of pain using a numeric

Table 1 Comparison of diagnostic modalities for sympathetically maintained pain

Technique	*Advantages*	*Disadvantages*
Interventional regional sympathetic block with local anesthetic agents (LASBs)	1. Well-localized sympathetic ganglion or chain can be anesthetized (blocked). Objective signs of sympathectomy are seen with small doses of LA 2. Systemic side effects from intravenous medications are avoided	1. Requires technical expertise and has higher cost 2. Requires fluoroscopy or CT guidance 3. Complication from contrast or medication allergy 4. Complication from technical reasons; e.g., infection, bleeding, and nerve damage 5. Poorly tolerated in pediatric population and patients with needle phobia 6. Sedatives used during the interventional technique might hinder with postprocedure pain responses 7. False negative • LA fails to anesthetize the sympathetic ganglion adequately • Intravascular injection • Central sympathetic–nociceptive interactions may be missed 8. False positive • LA anesthetizing somatic afferent fibers in the vicinity and causing pain relief from concurrent somatic blockade • Regional ischemic pain will improve with sympathetic block • Placebo effect
Intravenous regional sympathetic blockade (IRSB)	1. Easy to perform 2. Better patient acceptance 3. Low cost 4. Intravenous medications like phentolamine can cross blood–brain barrier and act on spinal cord α-2 adrenergic receptors, which are involved in pain modulation	1. Side effects of medications, e.g., phentolamine can cause positive chrontropic and inotrophic effects 2. Achieving complete sympathectomy at clinically tolerable doses might be difficult 3. Placebo effect cannot be ruled out

pain score before and after sympathetic blockade. The response is usually considered to be positive when a 50% or greater improvement in pain scores is reported in the light of adequate sympathectomy. LASB is traditionally considered as the gold standard against which other techniques have been tested in past (Dellemijn, P. L. *et al.*, 1994). Beyond CRPS, LASBs are also used to block efferent sympathetic fibers at thoracic sympathetic trunk, celiac plexus, superior hypogastric plexus, and ganglion impar to confirm improvement in pain prior to more invasive therapeutic blocks. These invasive procedures are used in the treatment of cancer pain, which may be somatic or visceral, and neuropathic or mixed in nature. A positive response to a temporary diagnostic local anesthetic block is a useful predictor of the success of subsequent neurodestructive procedures. Differential spinal or epidural blocks have also been described to distinguish somatic or central mechanisms from sympathetic etiologies. However, it is difficult to achieve selective sympathetic blockade with these techniques.

5.18.3.2 Intravenous Regional Sympathetic Blockade

Intravenous regional anesthesia, a technique described by August Bier in 1908, involves injection of a local anesthetic solution in a limb, isolated by tourniquet. Based on this concept, Hannington-Kiff proposed IRSB using guanethidine. Initially, guanethidine (with or without a local anesthetic agent) was used to perform this block and later other medications were tried. These include sympatholytics like reserpine, bretylium, or clonidine; local anesthetics like prilocaine or lidocaine; and others like kitanserin (5-HT2 antagonist). Although IRSBs have been used therapeutically in SMP, their use in diagnostic blocks has been limited. The ischemic tourniquet used during the procedure can itself relieve hyperalgesia in neuropathic pain patient (Campbell, J. N. *et al.*, 1988) and cause false-positive results. Certain patients tolerate tourniquet poorly. With IRSBs, guanethidine is often coinjected with local anesthetics since the release of norepinephrine by guanethidine is usually associated with the exacerbation of pain. As a result, diagnosis is often confounded by the effects of local anesthetics. Sudden release of tourniquet might release high doses of medications in systemic circulation and cause significant side effects. This technique is, hence, not useful as a diagnostic tool.

5.18.3.3 Systemic Alpha-Adrenergic Blockade

Intravenous alpha-adrenergic blockade with phentolamine (Phentolamine block, PhB) has been proposed as a safe and effective method of diagnosing SMP (Raja, S. N. *et al.*, 1991; Dellemijn, P. L. *et al.*, 1994). This technique is different from IRSB as no tourniquet is used to isolate the affected limb. In the initial study by Raja S. N. *et al.* (1991), 20 patients were randomly assigned to 25–35 mg of intravenous phentolamine (being administered in a double-blinded fashion) or LASB with 0.25% bupivacaine, and similar pain relief patterns were observed. Although 5–7 °C temperature difference was seen following LASB, the changes in cutaneous temperature after PhB were variable (1.8 ± 0.7 °C). Similar results were obtained by Dellemijn P. L. *et al.* (1994) who concluded that phentolamine infusion is less sensitive but more specific test of SMP than LASB. Both groups (Raja, S. N. *et al.*, 1991; Dellemijn, P. L. *et al.*, 1994) mentioned that the mechanism of pain relief during sympathetic blockade was independent of cutaneous vasodilatation or skin temperature changes. In an attempt to find optimum test dose, Raja S. N. *et al.* (1996) then compared the effect of two different doses of phentolamine (0.5 and 1 mg kg^{-1}) on skin blood flow (using a laser Doppler blood flow monitor) and sympathetically mediated vasoconstrictor response (a reflex decrease in peripheral blood flow in response to deep inhalation) (Raja, S. N. *et al.*, 1996). They concluded that the higher dose of phentolamine (1 mg kg^{-1} over 10 min) resulted in more complete adrenoceptor blockade and recommended this higher dose with cutaneous temperature monitoring to evaluate the sympathetically mediated component in neuropathic pain states.

There is a paucity of research in recognition of placebo responsiveness to sympathetic blocks. Randomization of patients for interventional techniques not only is difficult but also has ethical implications. Clinical observation frequently shows prolonged benefit in some patients beyond the duration of action of local anesthetic agents. Although reversal of central sensitization in the spinal cord and reduced coupling of sympathetic and sensory neurons have been put forward as a possible explanation, other possibilities need further consideration. In order to reduce placebo responsiveness, patients should have different diagnostic procedures like LASB and PhB on separate days. These two

procedures provide complementary information and both may be needed to confirm the diagnosis of SMP (Dellemijn, P. L. *et al.*, 1994).

5.18.4 Sympathetic Block for Therapy of Chronic Pain States

In the past, once diagnosis of SMP was established, patients were often offered a series of regional or intravenous blocks in attempt to reduce pain and vasomotor symptoms. At present, they are considered as an element of multidisciplinary treatment plans. Patients who get significant benefit from initial blocks are often subjected to more aggressive interventional therapies. These treatment modalities are presumed to have enduring sympathectomy or modulation of SNS. They include spinal cord (dorsal column) stimulation, chemical neurolytic procedures, radiofrequency denervation of sympathetic trunk, or even surgical sympathectomy.

5.18.4.1 Local Anesthetic Sympathetic Blocks and Intravenous Regional Sympathetic Blockade

LASBs provide short-term benefits in relieving spontaneous and evoked pain and reducing vasomotor symptoms. Their long-term efficacy is unproven. In contrast, IRSB does not require any special expertise, is easier to perform and, comparatively, has better patient acceptance (Table 1). These procedures have the risk of tourniquet-related pain (if used) and significant side effects from the medications. Both techniques can get false-positive results from placebo effect.

Randomized controlled trials (RCTs) are considered as gold standard to evaluate the efficacy of any therapeutic modality, but not many of these studies have been conducted to assess the usefulness of LASB in SMP. Most randomized trials have been done in CRPS patients (includes both SMP and SIP patients) and not specifically in SMP states. SIP patients are not expected to get any long-term benefits from sympathetic blocks and their inclusion in the study biases the results. Cepeda M. S. *et al.* (2002) attempted a systematic review of RCTs of the effect of LASB in CRPS (not SMP) patients but were unable to pool data due to significant differences in their design. The authors then reviewed nonrandomized controlled studies, case series, and RCTs with acceptable designs, published in English-language peer review journals from 1916 through 1999. Only 29 studies met the inclusion criteria of a sample size of at least 10 patients undergoing LASB with convincible evidence of CRPS. Interestingly, of these 29 studies, only 10 studies evaluated the technical success of block and only two of those assessed pain and outcome. Based on the data from 14 studies (454 patients) that quantified the magnitude of patient's responses and also reported the number of patients with different degrees of responses, authors found that 29% patients undergoing LASB obtain full pain relief (>75% improvement) while 41% obtain partial relief (25–75% improvement). Authors concluded that less than one-third positive response (full pain relief) is consistent with placebo effect and that the efficacy of sympathetic blocks for treatment of CRPS is inconclusive. Many of these 14 studies were published prior to 1960 and only two actually identified technical success of block and pain scores.

Long-term usefulness of IRSB is even less certain. Jadad A. R. *et al.* (1995) attempted a small RCT (nine patients) of the effects of repeated intravenous guanethidine blocks on pain intensity and relief, adverse effects, mood, duration of analgesia, and global scores. The trial was stopped prematurely because of the severity of the adverse effects (hypotension). No significant difference was found between guanethidine and placebo on any of the outcome measures. The authors also presented a systematic review of seven studies on the effects of IRSB in CRPS. Two of these studies, one using ketanserin and one bretylium, with 17 patients in total, showed some advantage over control but few other RCTs showed lack of efficacy of guanethidine. Authors concluded that the use of guanethidine in IRSBs for patients with CRPS was not supported by any available literature. A recent study by Livingstone *et al.* again showed no significant analgesic advantage of guanethidine over a normal saline placebo block in the treatment of early CRPS type I.

Difficulty in conducting RCTs for LASBs or IRSBs for treatment of CRPS or SMP is explicable. Randomization to placebo is almost impossible. Patients or physicians cannot be blinded as outcomes of adequate sympathectomy are obvious. Also, ethical issues might arise in performing technically challenging procedures like stellate ganglion block with saline. But randomization can be done in a different fashion. The new concept of expertise-based RCTs might be useful in this condition when patient outcomes can be compared between physicians who perform repeat LASBs or IVRBs to those who solely

impose conservative management. But again, such studies should compare patients with documented diagnosis of SMP and not CRPS. Based on available data in literature, efficacy and duration of LASB is variable and, indeed, unpredictable. Short duration of pain relief and reduction in vasomotor symptoms is often seen in clinical practice and should be utilized to improve mobility, range of motion, and motor strength by physiotherapy. Repeated blocks are beneficial in selected patients with willingness to actively participate in physiotherapy and are showing signs of continuing improvement.

5.18.4.2 Spinal Cord Stimulation

Spinal cord stimulation (SCS) has recently gained acceptance for a wide variety of neuropathic pain syndromes. A recent RCT (Kemler, M. A. *et al.*, 2004) and meta-analysis of literature (Grabow, T. S. *et al.*, 2003) showed that SCS results in a long-term pain reduction and health-related quality-of-life improvement, but no clinically important improvement of functional status, in chronic RSD. The technique is more effective and less expensive when compared with the standard treatment protocol for chronic CRPS (Mekhail, N. A. *et al.*, 2004). The mechanism of action by which the device provides pain relief is unclear. In general, patients with good response to sympathetic blocks are likely to have long-term pain relief (Hord, E. D. *et al.*, 2003) with SCS, although it does not affect skin microcirculation. The readers are encouraged to read a recent review on this subject for a detailed discussion (Meyerson, B. and Linderoth, B., 2001).

5.18.4.3 Chemical Neurolysis and Radiofrequency Denervation Techniques

Patients who show good response to initial sympathetic blocks are often subjected to radiofrequency denervation or chemical neurolytic destruction of sympathetic innervation. The technique of radiofrequency denervation has gone through various modifications by Noe *et al.*, Rocco, and Sluitjer. At present, destruction of T2 and T3 ganglions is recommended for upper extremity involvement while guidelines for lower extremity vary. Most authors suggest destruction of at least the first three ganglions (L1, L2, and L3), whereas others believe that the L4 and even L5 must be included for good long-term results. Complications of neurodestructive procedures include postsympathectomy sympathalgia, compensatory hyperhidrosis, Horner's syndrome, wound infection, and spinal cord injury. There is a theoretical advantage of lesser incidence of postsympathetic neuralgia and more precise sympatholysis with radiofrequency technique in comparison with chemical neurolysis. Outcome data for these techniques vary. While Wilkinson H. A. (1996) reported almost 90% partial or complete evidence of sympathectomy after 2 years, most authors report sustained pain relief in less than two-thirds of patients at 2 years, and about one-third at 5 years. In a systematic review of the effects of percutaneous neurodestructive procedures for neuropathic pain, Mailis A. and Furlan A. (2003) concluded that the practice of surgical and chemical sympathectomy is based on poor quality evidence, uncontrolled studies, and personal experience. Therefore, more clinical trials of sympathectomy are required to establish the overall effectiveness and potential risks of this procedure. Because of the limited long-term outcomes, consideration should be given to neuromodulatory methods for SMP involving extremities. For other SMP syndromes, like visceral neuropathic pain in pancreatic cancer, chemical neurolyis continues to be the procedure of choice.

5.18.4.4 Surgical Sympathectomy

Surgical sympathectomy has been tried in patients who achieve good pain relief with a series of sympathetic block. Better outcomes are predicted when sympathectomy is performed early in the disease. Concerns about recurrence or development of new CRPS or disabling compensatory sweating syndrome have been raised after surgical sympathectomy, but current data suggests low incidence (7%) of these complications (Bandyk, D. F. *et al.*, 2002). Other disturbing complication includes transient (<3 months) postprocedural sympathalgia (in one-third of the patients following cervicodorsal sympathectomy and 20% of the patients after lumbar sympathectomy). At 1 year postprocedure, one-quarter of the patients are expected to continue experience significant improvement (pain severity score <3) and an additional 50% of the patients would have continued but reduced pain severity and an increase in daily/work activities (Bandyk, D. F. *et al.*, 2002). Many surgeons prefer video-assisted minimally invasive techniques instead of open sympathectomy to reduce other complication rates and promote early postoperative recovery. With the increasing popularity of radiofrequency procedure, rates of surgical sympathectomy have decreased.

5.18.5 Conclusions

SNS plays an intriguing role in maintaining pain in certain conditions. Complex regional pain syndromes are prime example of such states. Selective sympathetic blocks are commonly used to diagnose a subset of patients with a predominant sympathetically maintained pain state. In order to avoid false-positive diagnosis, at least two different diagnostic tests should be implicated on separate days to confirm the diagnosis. Treatment options that have shown some promising results include local anesthetic sympathetic blocks, SCS, radiofrequency techniques, and surgical sympathectomy in early stages. Visceral pain of pancreatic origin responds well to chemical neurolytic blocks. More randomized trials are warranted to prove long-term efficacy of neuromodulation as well as neurodestructive techniques.

Glossary

Aβ nociceptors They have often been ignored but there is accumulating evidence that a subpopulation of large-diameter fast-conducting (A) sensory neurons are nociceptive (Djouhri, L. and Lawson, S. N., 2004).

calcitonin gene-related peptide (CGRP) It is a neuropeptide present in the majority of peptidergic primary afferent nociceptor neurons. CGRP is also expressed in some medium to large diameter afferent neurons and appears *de novo* in others. including gracile-projecting mechanosensitive neurons, after nerve injuries (Ma, W. *et al.*, 1999).

galanin It is a neuropeptide present in a subpopulation of CGRP-containing primary afferent nociceptor neurons. It is upregulated both in these neurons and in sympathetic postganglionic neurons after a peripheral nerve injury.

neuropeptide Y (NPY) It is a neuropeptide that is present in many sympathetic postganglionic vasoconstrictor neurons in most species. It is upregulated in gracile-projecting low-threshold mechanosensitive primary afferent neurons after peripheral nerve lesions.

nonpeptidergic sensory neurons These are small-diameter dorsal root ganglion neurons that lack any known neuropeptide but express GFRα1-2 and c-RET, components of the receptor complex for glial-derived neurotrophic factor, and bind isolectin B4 (derived from *Griffonia simplicifolia*) (Bennett, D. L. *et al.*, 1998), neither of which are features of peptidergic sensory neurons. Nonpeptidergic sensory neurons are usually nociceptive (Lawson, S. N., 2002).

p75 It is the low-affinity nerve growth factor (NGF) receptor recognized by NGF, brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4/5 (NT-4/5). p75 interacts with each neurotrophin but with slightly different binding properties. It has striking structural homology with a family of receptors, including tumor necrosis factor (TNF) receptors, CD40, and Fas, consistent with it having many functions.

peptidergic sensory neurons These are small-diameter dorsal root ganglion neurons that contain a known neuropeptide (such as substance P, calcitonin gene-related peptide, galanin, somatostatin, and vasoactive intestinal polypeptide) and are usually nociceptors (Lawson, S. N., 2002).

perineuronal rings or baskets These are arrangements of varicose nerve terminals formed by the endings of sympathetic neurons and peptidergic and nonpeptidergic sensory neurons within dorsal root ganglia that project into a lesioned nerve trunk.

retrograde reaction Refers to the response in the soma of a neuron when its axon is severed. Following axotomy, either a positive signal of injury or the arrest of the normal retrograde traffic from the axon terminals reaches the soma within a few hours via the retrograde axoplasmic transport mechanism. The neuron soma swells and the nucleus may assume an eccentric position. These structural changes are referred to chromatolysis as the chromophilic Nissl bodies are disrupted. Protein synthesis is modified so that synthesis of neurotransmitter substances is reduced and other

activities such as regeneration are supported. The satellite glia around the soma also respond and begin to release cytokines and chemokines. They proliferate and start to synthesize neurotrophins.

satellite glia These are the support cells that surround the cell bodies of primary afferent neurons within dorsal root ganglia. They normally express low levels of glial fibrillary acidic protein (GFAP) which is upregulated after nerve injury prior to the cells proliferating around damaged neurons.

substance P (SP) It is a neuropeptide present in a subpopulation of peptidergic primary afferent nociceptor neurons. It is upregulated in gracile-projecting low-threshold mechanosensitive primary afferent neurons after peripheral nerve lesions.

5.19.1 The Discovery

Clinicians observe that, in a subgroup of patients with chronic neuropathic pain after peripheral nerve injury of varying degrees of severity, sympathetic activity exacerbates or initiates pain, usually described as burning or stabbing (Bonica, J. J., 1990). The pain can be referred to superficial and/or deep sites and is often associated with allodynia and hyperalgesia. It has been postulated that, after the injury, nociceptors are activated by norepinephrine released by sympathetic activity, for example, during emotional stress or exposure to low environmental temperatures. This idea was based on evidence that pain was relieved by blockade of (1) the activity of sympathetic postganglionic neurons by injecting local anesthetics into paravertebral ganglia supplying the affected limb (Bonica, J. J., 1990), (2) norepinephrine release by injecting guanethidine into the limb (Wahren, L. K. *et al.*, 1991), or (3) the effects of norepinephrine by injecting α-adrenoceptor antagonists such phentolamine intravenously (Raja, S. N. *et al.*, 1991). Sympathetically maintained pain usually develops days to weeks after the injury.

These observations are mysterious because sympathetic nerve terminals are not co-located with nociceptor neurons or their terminals. In the skin, sympathetic axons terminate on arteriolar vessels deep within the dermis whereas nociceptor terminals lie below and within the epidermis. Sensory and sympathetic terminals do not usually co-locate in deeper tissues, other than rare axons containing substance P (SP) and calcitonin gene-related peptide (CGRP) that run among the sympathetic perivascular terminals on blood vessels (Holzer, P., 1992). There is no evidence for α-adrenoceptors on nociceptor terminals in normal skin and subcutaneous introduction of norepinephrine produces blanching but no pain.

Following early studies triggered by military injuries, an explosion of research in the last 25 years has utilized mainly rodents with injuries to one sciatic nerve that lead to diverse alterations in the damaged neurons, their supporting glia, the tissues they previously supplied, and the related vasculature. In addition inflammatory cells invade, not only the lesion site, but also retrogradely along the nerve trunk and within L4/5 dorsal root ganglia (DRGs), L3/4 sympathetic paravertebral ganglia, and the ventral horn of L4/5 spinal cord (Aldskogius, H. and Kozlova, E. N., 1998; Hu, P. and McLachlan, E. M., 2002; 2004). These changes persist for many months unless the damaged axons can regenerate to their target tissues.

Of relevance to injury-induced spontaneous pain is the generation of spontaneous activity in 20–30% of primary afferents within the damaged nerve. This activity is thought to contribute to central sensitization in the dorsal horn leading to abnormal discharge of nociceptive pathways (Mannion, R. J. and Woolf, C. J., 2000). The ectopic activity arises at two sites: in unmyelinated (C) neurons, it is initiated at the site of the injury (Michaelis, M. *et al.*, 1995); in myelinated (A) neurons, it arises from oscillations in the membrane potential of the somata in the DRG (Kajander, K. C. *et al.*, 1992; Liu, C. N. *et al.*, 2000). When the DRG and its connections are intact *in vivo*, activity in A axons arises in muscle but not cutaneous afferents (Michaelis, M. *et al.*, 2000).

The ectopic discharge in some DRG neurons can be generated or modulated by sympathetic activity. Wilfrid Jänig recorded from single myelinated afferent axons projecting down a ligated sciatic nerve (McLachlan, E. M. *et al.*, 1993). Stimulation of the sympathetic supply at high frequency (50 Hz for 10 s) excited a subgroup of afferents. Intravenous application of phentolamine completely inhibited the response, confirming that the sympathetic-sensory link was

located proximally. Histochemical demonstration of norepinephrine revealed perivascular terminals outside the ganglion sprouting through the DRG (McLachlan, E. M. *et al.*, 1993). After a few weeks, some sprouting axons had formed interwoven baskets or rings of varicose terminals around a few large-diameter neurons. These novel structures appeared to be the anatomical basis for a functional link between sympathetic and sensory systems after injury.

5.19.2 Sprouting of Sympathetic Axons within Dorsal Root Ganglia

Sprouting of norepinephrine-containing terminals into DRGs after injury was soon confirmed in many laboratories (e.g., Chung, K. *et al.*, 1996; Kim, H. J. *et al.*, 1996; Ramer, M. S. and Bisby, M. A., 1997), mainly using immunohistochemistry to demonstrate tyrosine hydroxylase (TH), the rate-limiting enzyme for the synthesis of norepinephrine. The time course of development of sprouts varies with the site and nature of the lesion (Ramer, M. S. *et al.*, 1999). In rats, the sprouts develop over a few weeks after sciatic transection and form increasing numbers of perineuronal rings after ~4 weeks. The number of rings reaches a maximum (~2.5% of neurons or ~7.5% of A neurons) between 8 and 12 weeks and then gradually declines over 1 year or more (Hu, P. and McLachlan, E. M., 2001). While sympathetic sprouts appear in normal aged animals (Ramer, M. S. and Bisby, M. A., 1998b), this cannot account for the raised proportion of rings on the side ipsilateral to the lesion. Some perineuronal rings may persist indefinitely after injury, probably accounting for their presence in humans as described by Ramon y Cajal (Garcia-Poblete, E. *et al.*, 2003). The extent of sprouting is generally greater if the lesion is closer to the DRG (Kim, H. J. *et al.*, 1996; Ramer, M. S. and Bisby, M. A., 1998a) and if more axons are cut (Kim, H. J. *et al.*, 2001), although the relationships are not linear and may depend on the proportions of cutaneous and muscle axons involved (Hu, P. and McLachlan, E. M., 2003). Sprouting of sympathetic terminals into DRGs after sciatic transection does not occur in guinea-pigs that lack sympathetic terminals on nearby vessels (Hu, P. and McLachlan, E. M., 2000).

Sympathetic sprouts are already quite extensive after 7 days if the spinal nerve is transected (Chung, K. *et al.*, 1996; Ramer, M. S. *et al.*, 1998). Cutting L5 spinal nerve leads to hyperalgesia within a few days in the territory of the intact root (L4). Sympathetic sprouts appear sooner and are more prolific when the sciatic nerve is only partially transected (Shir, Y. and Seltzer, Z., 1991) or subjected to chronic constriction (CCI) (Bennett, G. J. and Xie, Y. K., 1988) rather than transection. These injuries, like spinal nerve transection, leave intact axons lying in regions of Wallerian degeneration and the ensuing inflammatory reaction damages more axons. Such injuries produce mechanical allodynia and thermal hyperalgesia within a few days.

5.19.3 Sprouting of Primary Afferent Neurons within Dorsal Root Ganglia

One possible trigger for sprouting of perivascular terminals is an increased local concentration of neurotrophins, such as nerve growth factor (NGF) (Herzberg, U. *et al.*, 1997; see below). Consistent with this, sensory neurons containing SP and CGRP which bear the appropriate receptors (trkA) sprout within the lesioned DRG, forming similar numbers of perineuronal rings (McLachlan, E. M. and Hu, P., 1998). Galanin appears in some sprouts of both sympathetic and peptidergic origin (Hu, P. and McLachlan, E. M., 2001).

There is one report (Li, L. and Zhou, X. F., 2001) that the nonpeptidergic primary afferent axons that bind *Griffonia simplicifolia* I isolectin B4 (IB4) also sprout within L5 DRG after spinal nerve transection. Increasingly from 5 weeks after the lesion, IB4+ axons were found to encircle mainly large-diameter neuron somata where they were intermingled with proliferated satellite cells that also bound IB4. In some cases, TH+ axons were present around the same neurons. What is amazing is that tenfold more neurons received IB4+ perineuronal rings than TH+, CGRP+, or galanin+ rings at the same postoperative time (McLachlan, E. M. and Hu, P., 1998; Hu, P. and McLachlan, E. M., 2001). However, only a few of the IB4+ axons also stained for protein gene product (PGP) 9.5, a pan-neuronal marker (ubiquitin C-terminal hydroxylase).

5.19.4 Formation of Perineuronal Rings or Baskets

Perineuronal rings form more often at either pole of the DRG where large-diameter neurons are clustered (McLachlan, E. M. *et al.*, 1993). The neurons that receive them can be axotomized or intact (Jones, M. G. *et al.*, 1999; Hu, P. and

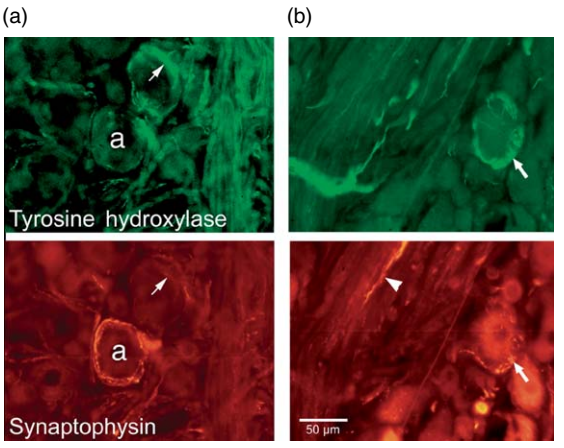

Figure 1 Perineuronal rings in rat L5 dorsal root ganglia 10 weeks after sciatic nerve transection and ligation. Two pairs of micrographs (a) and (b) show immunofluorescence for tyrosine hydroxylase (TH, green) and synaptophysin (Syn, red). (a) TH+ terminals that lack Syn (thin arrows) wrap around a neuron soma adjacent to another (A) that bears a dense basket of Syn+ terminals. (b) A neuron receives a TH+/Syn+ perineuronal ring (thick arrows). TH+ axons in the small nerve bundle to the left in (b) do not express Syn but a sprouting axon in the main axon bundle (arrowhead) is Syn+.

McLachlan, E. M., 2003). The varicose terminals intertwine around the somata but normally remain within the layers of proliferated satellite glia, very rarely forming contact with neuron somata (Chung, K. *et al.*, 1997; Shinder, V. *et al.*, 1999).

Sometimes isolated neurons are targeted, or more than one type of axon can encircle the same neuron (McLachlan, E. M. and Hu, P., 1998) or, in other cases, adjacent neurons receive a ring from one or other axon type (Figure 1). Synaptophysin, a non-specific marker of sprouting axons, appears in rings at a similar density to those with TH, CGRP, or galanin (Hu, P. and McLachlan, E. M., 2003). This may result because synaptophysin is only partly co-located with these substances or because of nonpeptidergic axon sprouts. As synaptophysin is also a synaptic vesicle protein, its presence in some but not all varicosities within rings supports them being release sites. Unfortunately, it is likely to be impossible to measure release directly from these terminals.

5.19.5 Underlying Cellular Mechanisms

Systemic lidocaine is successful in treating some forms of neuropathic pain (Wallace, M. S. *et al.*, 2000). Delivery of lidocaine by osmotic pump to rats with nerve transection reduced the amount of sympathetic sprouting and the number of TH+ rings (Zhang, J. M. *et al.*, 2004), as did its application locally at the time of the lesion. These data suggest that activity derived from the neuroma is important for initiating the sprouting response.

Sympathetic axons sprout from two sources: (1) from intact perivascular terminals, which occur after a distant lesion, and are dependent on NGF and (2) by retrograde growth along the spinal nerve, which occurs when anterograde growth is obstructed at the lesion, and is NGF-independent. The former predominates after a distant injury, and the latter after spinal nerve ligation (Ramer, M. S. and Bisby, M. A., 1999). However, a common response to axotomy is the sprouting of collaterals from a transected axon within a short distance from the soma (Kelly, M. E. M. *et al.*, 1989) and this may occur after lesions to either sympathetic or sensory axons.

Upregulation of neurotrophin messenger ribonucleic acid (mRNA) by satellite glia leads to their local production within the DRG, stimulating growth of axons bearing appropriate receptors. This has been shown for NGF and neurotrophin-3 (NT-3) which are synthesized by the proliferated satellite glia that surround large-diameter neurons. Treatment with antibodies to NGF or NT-3 reduces the length of TH+ sprouts after a spinal nerve lesion (Ramer, M. S. and Bisby, M. A., 1999; Zhou, X. F. *et al.*, 1999) as both trkA and trkC are present on sympathetic and sensory axons. Brain-derived neurotrophic factor (BDNF) is upregulated in lesioned DRG neurons and antibodies to BDNF also inhibit sympathetic sprouting (Deng, Y. S. *et al.*, 2000). These approaches do not seem to have been applied to examine sprouting of sensory neurons. Glial cell-derived neurotrophic factor (GDNF) mRNA is present in satellite cells in DRGs and is upregulated after injury (Hammarberg, H. *et al.*, 1996), providing a basis for the sprouting of IB4+ axons (Li, L. and Zhou, X. F., 2001). Intrathecal GDNF does not elicit sympathetic sprouts (Jones, M. G. *et al.*, 1999) but leukemia inhibitory factor does (Thompson, S. W. and Majithia, A. A., 1998), perhaps by an effect that modifies NGF production.

The formation of perineuronal rings has been studied in trigeminal ganglia of transgenic mice. When these animals overexpress NGF (Davis, B. M. *et al.*, 1994), TH+ terminals preferentially target trkA+ CGRP+ sensory neurons that contain NGF (Walsh, G. S. and Kawaja, M. D., 1998; Walsh, G. S. *et al.*, 1999). The data indicate that CGRP+ axons do not

sprout in these animals. If NGF or trkA is deleted, the TH+ axons do not enter the ganglion. If p75 is deleted but NGF is overexpressed, abundant TH+ sprouts wander through the DRG without associating with specific neuron somata (Walsh, G. S. *et al.*, 1999).

These elegant experiments do not help to explain sprouting or the formation of rings after nerve injury in normal adult animals. As mentioned above, NGF is synthesized by satellite glia that express p75 whereas trkA is downregulated on neuron somata (Verge, V. M. *et al.*, 1989). Further, no sprouts appear in the rat trigeminal ganglion after transection of the infraorbital or inferior alveolar nerve quite close to the ganglion (Bongenhielm, U. *et al.*, 1999) or chronic constriction injury (CCI) of the mental nerve (Grelik, C. *et al.*, 2005). This seems surprising as sympathetic axons join the nerve immediately distal to the trigeminal ganglion as for the DRG. Perhaps the absence of large-diameter proprioceptive neurons (located in the mesencephalic nucleus V) prevents the changes that trigger sympathetic sprouting in lesioned DRGs. Whether peptidergic neurons in trigeminal ganglia sprout after nerve lesions does not seem to have been examined.

Nevertheless it seems likely that the expression of p75 on proliferated glia in rat DRGs is important for ring formation. In guinea-pigs, in which sympathetic sprouting does not occur (see above), peptidergic axons sprout into the DRG but do not form perineuronal rings after sciatic transection. This might be explained by both the absence of glial reaction to axotomy (i.e., no upregulation of glial fibrillary acidic protein) and the failure of glia to express p75 in this species (Hu, P. and McLachlan, E. M., 2000).

What initiates neurotrophin production? It might follow the retrograde reaction in satellite glia and the subsequent invasion of the DRG by macrophages and lymphocytes (Hu, P. and McLachlan, E. M., 2002). Following sciatic transection, macrophage and T-cell density peaks after 1 week and remains raised for several months. Lymphocytes and macrophages secrete neurotrophins and proinflammatory cytokines. Neurotrophins trigger sprouting and cytokines sensitize DRG neurons. Further, T cells contribute to injury-induced pain (Moalem, G. *et al.*, 2004).

5.19.6 Other Functional Considerations

The somata around which perineuronal rings form have been thought to be low-threshold mechanoreceptors. The absence of sympathetic rings around peptidergic neurons (Ramer, M. S. and Bisby, M. A., 1998c) excludes the gracile-projecting A neurons which express SP, CGRP, NPY, and galanin several weeks after a peripheral injury (Zhang, X. *et al.*, 1993; Noguchi, K. *et al.*, 1995; Ma, W. and Bisby, M. A., 1997; Ma, W. *et al.*, 1999). Varicose peptidergic rings do not form around peptidergic neurons (McLachlan, E. M. and Hu, P., 1998). However, ~20% of A neurons in rat L5 DRG are Aβ-nociceptors (Djouhri, L. and Lawson, S. N., 2004) that is, 6% of all neurons, and at least some have large diameters. Allowing that TH+ terminals make up only ~50% of rings, rings may occur on 6% of neurons, making it feasible that Aβ-nociceptor neurons are the targets. While trkA is currently the only specific marker of these Aβ-neurons (Fang, X. *et al.*, 2005), this is downregulated after axotomy (Verge, V. M. *et al.*, 1989; Li, L. *et al.*, 2000) so that it may not be possible to test this idea.

Despite evidence that α-adrenoceptors are expressed *de novo* by a small proportion of largely medium-diameter neurons in lesioned DRGs (Birder, L. A. and Perl, E. R., 1999), there is limited evidence that norepinephrine can excite lesioned A neurons. Although norepinephrine can depolarize a small proportion of both control and damaged neurons in intact DRGs *in vitro* (Jones, M. G. *et al.*, 1999), this does not seem to be α-adrenoceptor mediated (Lopez de Armentia, M. *et al.*, 2003; cf. Xing, J. L. *et al.*, 2003). For neuropeptides, neuron somata with myelinated axons lack CGRP binding sites (Segond von Banchet, G. *et al.*, 2002), although they can develop sensitivity to galanin and SP after axotomy (Xu, Z. Q. *et al.*, 1997; Abdulla, F. A. *et al.*, 2001). This has not been demonstrated *in situ*.

5.19.7 Other Forms of Sympathetic Plasticity after Nerve Injury

Is there another explanation for the enhanced responses to sympathetic activation after injury? The normal consequence of sympathetic activity is vasoconstriction which is abolished by phentolamine. Stimulation paradigms that excite DRG neurons (>10 Hz) elicit marked vasoconstriction in most vascular beds. Stimulation of the lumbar sympathetic chain augmented discharge in a proportion of myelinated dorsal root axons from spinal nerve-injured rats only when vascular resistance in the

DRG was near maximal (Häbler, H. J. *et al.*, 2000). Discharge was also increased by vasoconstrictor agents and blockade of nitric oxide synthase. These data imply that enhanced neurovascular responses after a lesion jeopardize perfusion of the DRG, and raise the possibility that ischemia may be responsible for increasing excitability of sensory neurons.

Finally, the phenomenon of sympathetic sprouting in lesioned DRGs has had attention because of its possible relation to sympathetically maintained neuropathic pain. It is, however, important to note the failure of sympathectomy to modify ectopic activity in anesthetized rats (Liu, X. G. *et al.*, 2000) or mechanical allodynia (Ringkamp, M. *et al.*, 1999), and the lack of relation between the extent of sympathetic sprouting and pain behavior (Kim, H. J. *et al.*, 1999). Thus, although sympathetic perineuronal rings have been postulated to underlie ectopic activity, evidence for this in experimental animals is not convincing. Nevertheless the experiments on sprouting have provided insights into plasticity in the damaged nervous system.

Glossary

allodynia, hyperalgesia See Chapter Autonomic Nervous System and Pain.

angina (pectoris) A paroxysmal thoracic pain, with a feeling of suffocation and impending death, due, most often but not always, to anoxia of the myocardium.

GALT (gut-associated lymphoid tisue) Immune system of the gastrointestinal tract, in particular in the small intestine. It includes the immune cells of Peyer´s patches, M-cells of the epithelial lining modified entestinal epithelial cells (enterocytes), lyphocytes in the almina propria, macrophages, and mast cells. Its function is to defend the body against invading antigens from food, bacteria, parasites, and toxins.

neurogenic inflammation Peptidergic primary afferent neurons with unmyelinated fibers (some with small-diameter myelinated (A delta) fibers) generate upon excitation precapillary (arteriolar) vasodilation (by release of calcitonin gene-related peptide (CGRP) supported by release of substance P and neurokinin A) and postcapillary (venular) plasma extravasation (by release of substance P and neurokinin A). Originally venular plasma extravasation was called neurogenic inflammation, but both precapillary vasodilation and postganglionic plasma extravasation are collectively now called neurogenic inflammation.

referred pain See Chapter Autonomic Nervous System and Pain.

vagal afferents Afferents projecting through the vagal nerves. Most of their cell bodies are located in the inferior vagal (nodose) ganglion and a few in the superior vagal (jugular) ganglion.

1. Vagal afferents innervating the heart may be involved in pain during angina referred to the upper cervical dermatomes and myotomes.
2. Vagal afferents innervating the stomach and being excited by acid are involved in nociceptive protective reactions, but probably not in conscious perception of pain.
3. Transmission of nociceptive impulses in the spinal or trigeminal dorsal horn is under inhibitory control generated by activity in cardiopulmonary and/or abdominal vagal afferents.
4. Vagal afferents innervating the liver (thus passing through the hepatic branch of the abdominal vagus nerves) are involved in illness responses generated by lipopolysaccharides (LPS) (bacterial antigens) or proinflammatory cytokines (e.g., interleukin-1β (IL-1β) or tumor necrosis factor α (TNF-α)) into the peritoneal cavity. One component of the illness responses is hyperalgesic behavior.
5. Activity in abdominal vagal afferents innervating the small intestine and probably sensing toxic and other events in the gastrointestinal tract (GIT) may be involved in reflex modulation of inflammation and sensitivity of nociceptors in somatic tissues via the sympatho-adrenal system (releasing adrenaline) and possibly the hypothalamo-pituitary–adrenal system.

The response properties of vagal afferents to physiological stimuli being involved in the reflex modulation of nociception, pain, hyperalgesia, inflammation, and illness responses are unknown. It

is likely that not one functionally specific type of vagal afferent neuron is involved but several different types.

5.20.1 Introduction

The vagus nerves contain 80–85% visceral afferent fibers, most of them innervating the GIT, and 15–20% preganglionic parasympathetic fibers, at least in rats (Precht, J. C. and Powley, T. L., 1990; Berthoud, H. R. *et al.*, 1991). These afferent neurons are involved not only in organ regulation by the autonomic nervous system (Jänig, W., 2006) but also in the control of protective body reactions that include nociception and pain. These functions are inferred from various types of experimental investigations and from some clinical observations. It is unclear whether functionally specific groups of vagal afferents are involved in protective body reactions or whether vagal afferents being involved in organ regulation are also responsible for protective body reactions. In this chapter I will summarize:

1. data related to the role of vagal afferents in generating pain and in modulating central processing of nociceptive impulse activity and
2. data about the role of vagal afferents in protective reactions of the body including inflammation and hyperalgesia (Jänig, W., 2005; Jänig, W. and Levine, J. D., 2006).

5.20.2 Vagal Afferents, Pain, and Nociception

5.20.2.1 Thoracic Visceral Organs

Pain elicited from the proximal esophagus and proximal trachea is probably mediated by vagal afferents innervating the mucosa of these organs. These afferents are peptidergic (i.e., contain calcitonin gene related peptide (CGRP) and/or substance P); their cell bodies are probably located in the jugular ganglion (superior vagal ganglion; see Berthoud, H. R. and Neuhuber, W. L., 2000) cells in the nodose ganglion (inferior vagal ganglion) are almost exclusively peptide-negative, whereas neurons in the jugular ganglion may contain peptides). Activation of these afferents generates neurogenic inflammation in the mucosa (venular plasma extravasation and vasodilation (McDonald, D. M. *et al.*, 1988; McDonald, D. M., 1990)). Pain elicited from the more distal sections of esophagus and trachea as well as from the bronchi may be generated by stimulation of spinal visceral afferent neurons yet not of vagal afferents. However, this situation is unclear and needs further experimentation.

Cardiac pain (e.g., during ischemic heart disease) is considered to be mediated by activation of spinal visceral afferents having their cell bodies in the dorsal root ganglia C8–T9 (mainly T2–6). However, attempts to relieve cardiac angina pain by surgical interventions (cervico-thoracic sympathectomy, dorsal rhizotomy, injection of alcohol into the sympathetic chain) consistently showed that only 50–60% of patients report complete relief from angina while the remaining patients report either partial relief or no relief at all. Some failures to relief pain may have been attributed to incomplete spinal denervation of the heart; but vagal afferents innervating particularly the inferior–posterior part of the heart may mediate cardiac pain too (see Meller, S. T. and Gebhart, G. F., 1992).

Electrical stimulation of cervical vagal afferent fibers in rats modulates the nociceptive tail reflex as well as the responses of dorsal horn neurons in the lumbar spinal cord. Low-intensity electrical vagal stimulation, probably exciting mainly myelinated afferents, facilitates both whereas high-intensity stimulation, probably exciting mainly C-fibers, attenuates both (Randich, A. and Gebhart, G. F., 1992; Ren, K. *et al.*, 1993). Nociceptive reflexes in neurons of the trigeminal nucleus caudalis or oralis of rats were mainly suppressed during electrical stimulation of cervical vagal afferents (Bossut, D. F. and Maixner, W., 1996; Takeda, M. *et al.*, 1998). Neurophysiological investigations in monkeys and rats show that some spino-thalamic tract (STT) neurons in the superficial dorsal horn and deeper laminae of the cervical segments C1–C2 (C3) can be synaptically activated by electrical stimulation of cardiopulmonary spinal and vagal afferents or by injection of algogenic chemicals in the pericardial sac via both afferent pathways. The activation of the STT neurons by vagal afferents is relayed through the nucleus tractus solitarii. These STT neurons are also synaptically activated by mechanical stimulation of the somatic receptive fields in the corresponding segments from the head, jaw, neck, and shoulder (dermatomes, myotomes); this is fully in line with clinical observations showing that cardiac pain may be referred to neck, shoulder, and jaw (Lindgren, I. and Olivecrona, H., 1947; White, J. C. and Bland, E. F., 1948; Meller, S. T. and Gebhart, G. F., 1992). The dorsal horn of the same high cervical spinal

segments contains neurons with similar convergent synaptic inputs from vagal, spinal visceral, and somatic afferents that project to more caudal spinal thoracic, lumbar, and sacral segments. These dorsal horn neurons are involved in the inhibitory control of nociceptive impulse transmission (see Foreman, R. D., 1999; Chandler, M. J. *et al.*, 2002; see also Section 5.20.3, point 2).

Experimental studies on animals showing that nociceptive behavior and inhibition of nociceptive impulse transmission in the spinal and trigeminal dorsal horn is inhibited by electrical stimulation of the cervical vagus nerve have led to the idea that continuous electrical stimulation of vagal afferents could be used to treat chronic pain syndromes in patients. Electrical stimulation of the vagus nerve via a pair of electrodes implanted at the left cervical vagus nerve has been used recently in patients with some success to treat drug-resistant refractory epilepsy. The mechanisms underlying this antiepileptic effect are unknown (Schachter, S. C., 2005). A few experimental studies have been conducted on these patients to test whether experimental pain can be attenuated by vagal nerve stimulation. Furthermore, in patients with chronic headache (migraine, tension-type headache, cluster headache) electrodes have been implanted at the left cervical vagus nerve. In these experiments, in pilot studies, as well as in some case reports it has been shown that electrical vagal nerve stimulation may reduce experimental pain or relieve chronic headache (for literature and discussion see Multon, S. and Schoenen, J., 2005).

5.20.2.2 Pelvic and Abdominal Organs

Visceral pain elicited from pelvic and most abdominal organs is triggered by stimulation of spinal visceral afferent neurons and not by stimulation of vagal afferent neurons (Cervero, F., 1994; see Chapter Spinal Cord Mechanisms of Hyperalgesia and Allodynia). However, the situation is not entirely clear for the gastroduodenal section of the GIT. Whether patients with complete interruption of spinal ascending impulse transmission at the thoracic level T1 or at a more rostral segmental level can experience pain from the gastroduodenal section (e.g., during gastritis, a peptic ulcer, or distension of the stomach) has never been systematically investigated. Patients with complete lesion of the cervical spinal cord experience abdominal hunger, dread, and nausea (Crawford, J. P. and Frankel, H. L., 1971). Furthermore, these patients may experience vague sensations of fullness after a hot meal. But acid reflux or an obstructed or distended viscus usually does not generate discomfort and pain (Juler, G. L. and Eltorai, I. M., 1985; Strauther, G. R. *et al.*, 1999). An acute perforation of a duodenal ulcer may be accompanied by violent pain in the right or left shoulder (page 284 in Guttmann, L., 1976), indicating that vagal afferents may be involved.

It is generally accepted that stimulation of vagal afferents innervating the stomach elicits emesis, bloating, and nausea, all three being protective reactions. Experiments on rats show that influx of acid into and other chemical insults of the gastroduodenal mucosa lead to a host of locally and centrally organized protective reactions that are mediated by spinal visceral and vagal afferent neurons. Activation of vagal afferents by these chemical stimuli excites neurons in the nucleus tractus solitarii, area postrema, lateral parabrachial nucleus, subceruleus nucleus, thalamic and hypothalamic paraventricular nuclei, supraoptic nucleus, and central amygdala, but not in the insular cortex (the major central representation area of the stomach) as shown by the expression of the marker protein Fos (Michl, T. *et al.*, 2001). Furthermore, neurons in the spinal dorsal horn do not seem to be activated. Thus, vagal afferents innervating the gastroduodenal mucosa (Holzer, P. and Maggi, C. A., 1998; Holzer, P.; 2002; 2003; 2006) (1) seem to be involved in chemonociception, local protective reactions, and generation of autonomic, endocrine, and behavioral protective reactions but (2) not in pain perception, yet in the emotional aspect of pain and therefore indirectly in upper abdominal hyperalgesia.

These fascinating ideas, formulated by Holzer, need verification by further experimentation. For example, it is unclear in which way (1) activity in spinal visceral afferents and vagal afferents is centrally integrated *in vivo* so as to elicit the protective reflexes, protective behavior, and pain sensations including visceral hyperalgesia and (2) activity in vagal afferents is responsible for the emotional aspects of visceral pain, but spinal visceral afferents for the conscious perception of visceral pain.

5.20.3 Abdominal Vagal Afferents, Protection of the Body, and Illness Responses

The small intestine and liver are very vulnerable portals of entries into the body. Both have potent local defense systems and serve as internal defense

lines of the body. The small intestine contains a powerful immune system (the gut associated lymphoid tissue (GALT) (Shanahan, F., 1994)) that is innervated by vagal afferents projecting through the celiac branches of the abdominal vagus nerve. Specific modulation of activity in these afferents in conjunction with the reaction of the GALT may act as an early warning system to the rest of the body by transmitting important information to the brain about toxic events and agents in the small intestine that are dangerous for the organism (Berthoud, H. R. and Neuhuber, W. L., 2000). Thus, particularly vagal afferents in the celiac branches of the abdominal vagus nerves that innervate the small intestine (in addition to the distal duodenum and the proximal colon) and vagal afferents in the hepatic branch that innervate the liver (in addition to the proximal duodenum, pancreas, and pylorus) may be important for protective functions of the GIT and the body:

1. Vagal afferents in the celiac branches of the abdominal vagus nerve monitor chemical and mechanical events that occur in the intestine under physiological and pathophysiological conditions (for review see Grundy, D. and Scratcherd, T., 1989), that is, are related to meals, ingestion of toxic substances, inflammation, obstruction. These afferents respond to distension or contraction of the small intestine or to intraluminal chemical stimulation (e.g., maltose, glucose, protein products of long-chain lipids, or intraluminal osmotic stimuli). The responses to chemical stimuli are mediated by enterochromaffin cells releasing 5-HT and by 5-HT_3 receptors on the terminals of the vagal afferents (Zhu, J. X. *et al.*, 2001) or enteroendocrine cells releasing cholecystokinin (CCK) and the CCK_A receptor on the terminals of the vagal afferent neurons (Richards, W. *et al.*, 1996; Lal, S. *et al.*, 2001). Vagal afferent neurons may be associated with the GALT and may be excited by inflammatory processes and toxic processes, also probably mediated by enterochromaffin cells releasing serotonin (5-HT), enteroendocrine cells releasing CCK, or mast cells releasing histamine and other compounds (Kirkup, A. J. *et al.*, 2001; Kreis, M. E. *et al.*, 2002). The functional specificity of these afferents with respect to the different types of intraluminal stimuli is unknown. The vagal afferents are important for preabsorptive detection of energy-yielding molecules and probably for other properties of nutrient solutions that are toxic and deleterious for the GIT and for the body (Walls, E. K. *et al.*, 1995a; 1995b). Additionally, some vagal afferents that innervate the small intestine and the liver respond to cytokines (e.g., IL-1β); these afferents may encode events that are related to the immune system of the GIT and liver (Niijima, A., 1996).
2. Electrical stimulation of abdominal vagal afferents exerts inhibition or facilitation of central nociceptive impulse transmission in the spinal dorsal horn and depresses nociceptive behavior depending on as to whether unmyelinated or myelinated vagal afferents are excited (Randich, A. and Gebhart, G. F., 1992). Electrical stimulation of cervical vagal afferents in monkeys suppresses transmission of impulse activity in STT neurons with nociceptive function at all levels of the spinal cord. Electrical stimulation of subdiaphragmatic vagal afferents has no effect on STT neurons in this species, arguing that particularly cardiopulmonary vagal afferents are involved in this inhibitory control. The central pathways mediating the inhibitory effect are neurons in the subceruleus–parabrachial complex (noradrenergic) and neurons in the nucleus raphe magnus of the rostroventromedial medulla (serotonergic) that project to the spinal cord (Foreman, R. D., 1989). The central pathways mediating the facilitatory effect are mediated by suprapontine pathways (Gebhart, G. F. and Randich, A., 1992; Randich, A. and Gebhart, G. F., 1992). The functional types of vagal afferents being involved in inhibitory and facilitatory control of nociceptive impulse transmission are unknown.
3. Activity in vagal afferents innervating the small intestine (i.e., projecting through the celiac branches of the abdominal vagus nerves) is important in reflex modulation of inflammatory processes (e.g., in the knee joint) and mechanical hyperalgesic behavior (by sensitization of nociceptors) in remote body tissues involving the sympatho-adrenal system and possibly the hypothalamo-pituitary–adrenal system (Green, P. G. *et al.*, 1995; 1997; Miao, F. J.-P. *et al.*, 1997a;1997b; Khasar, S. G. *et al.*, 1998a; 1998b; Jänig, W. *et al.*, 2000; Miao, F. J. -P. *et al.*, 2000, Miao; F. J. -P.*et al.*, 2001; Khasar, S. G. *et al.*, 2003; Miao, F. J. -P. *et al.*, 2003a; 2003b; see Section 5.17.3.4.4 and 5.17.4 in Chapter Autonomic Nervous System and Pain.
4. Intraperitoneal injection of illness-inducing agents, such as the bacterial cell wall endotoxin LPS in rats, produces behavioral hyperalgesia.

This is mediated by activity in subdiaphragmatic vagal afferents, specifically afferents running in the hepatic branch. It is suggested that LPS activates hepatic macrophages (Kupffer cells), dendritic cells, and leukocytes that release IL-1β and TNF-α. This in turn activates vagal afferents from the liver. IL-1β and TNF-α injected intraperitoneally themselves generate behavioral hyperalgesia that is abolished by vagotomy (Watkins, L. R. *et al.*, 1994a; 1994b; 1995a; 1995b; 1995c; 1995d). The proinflammatory cytokines either activate the vagal afferents directly or bind to glomus cells in the abdominal paraganglia that are innervated by vagal afferents; the activated vagal afferents signal the peripheral events to the brain, leading to hyperalgesia (as shown by an enhanced thermal nociceptive tail-flick reflex).

5. Pain behavior mediated by vagal afferents, activated by intraperitoneal injection of LPS or of proinflammatory cytokines, is part of a general sickness behavior characterized by various protective illness responses (e.g., immobility, decreased social interaction, decrease in food intake, formation of taste aversion to novel foods, decrease of digestion, loss of weight (anorexia), fever, increase of sleep, change in endocrine functions (activation of the hypothalamo–pituitary–adrenal axis), malaise) and is correlated with marked alterations of brain functions. For example, food aversion and anorexia generated in rats by intraperitoneal TNF-α are abolished or attenuated by subdiaphragmatic vagotomy (Bret-Dibat, J. L. *et al.*, 1995; Bernstein, I. L., 1996). Endotoxin, IL-1β, or TNF-α injected intraperitoneally activate nodose ganglion cells (Gaykema, R. P. *et al.*, 1998) and various brain areas in rodents (nucleus tractus solitarii, parabrachial nuclei, and hypothalamic supraoptic and paraventricular nuclei) as well as induce IL-1β mRNA in the pituitary gland, hypothalamus, and hippocampus. These changes do not occur or are significantly attenuated in subdiaphragmatically vagotomized animals (Ericsson, A. *et al.*, 1994; Wan, W. *et al.*, 1994; Layé, S. *et al.*, 1995; see Sawchenko, P. E. *et al.*, 1996; Dantzer, R. *et al.*, 1998; 2000).
6. Watkins, Maier, and coworkers have developed the idea that vagal abdominal afferents projecting through the hepatic branch of the abdominal vagus nerves form an important neural interface between the immune system and the brain. Activation of these afferents by signals from the immune system (proinflammatory cytokines IL-1β, TNF-α, IL-6) trigger via different centers in brain stem and hypothalamus illness responses, one component being pain and hyperalgesia. The underlying mechanisms of these illness responses have been discussed (Maier, S. F. and Watkins, L. R., 1998; Watkins, L. R. and Maier, S. F., 1999, Goehler, L. E. *et al.*, 2000; Watkins, L. R. and Maier, S. F., 2000). The physiology of the vagal afferents involved in the communication between the immune system, which operates as a diffuse sensory system to detect chemical constituents associated with dangerous microorganisms and their toxins, and the brain has to be worked out.

Glossary

biopsychosocial model A model of pain that posits that the experience of and response to pain results from complex, dynamic interactions among biological, psychological, and sociocultural variables.

gender A person's self-representation as male or female, or how that person is responded to by social institutions on the basis of that individual's gender presentation.

sex The classification of living things, generally as male or female, according to their reproductive organs and functions assigned by the chromosomal complement.

5.21.1 Sex Differences in Pain Responses

Considerable evidence suggests that females and males differ in their experience of both clinical and experimentally induced pain (for reviews, see Fillingim, R. B. and Maixner, W., 1995; Unruh, A. M., 1996; Berkley, K. J., 1997; LeResche, L., 1999; Fillingim, R. B., 2003). For example, several chronic pain disorders are more prevalent among women, and in population surveys women report more pain than men (Fillingim, R. B. and Maixner, W., 1995; Unruh, A. M., 1996; Berkley, K. J., 1997). Moreover, some evidence indicates that clinical pain may be more severe for women than men. For example, women have reported greater postsurgical pain than men in some (Savedra, M. C. *et al.*, 1993; Averbuch, M. and Katzper, M., 2000; Coulthard, P. *et al.*, 2000; Taenzer, A. H. *et al.*, 2000; Morin, C. *et al.*, 2000; Averbuch, M. and Katzper, M., 2001; Kalkman, C. J. *et al.*, 2003) but not all (e.g., Gordon, N. C. *et al.*, 1995; Gear, R. W. *et al.*, 1996a; Chia, Y. Y. *et al.*, 2002) studies. Women have also reported higher pain ratings in acute cancer-related pain (Cepeda, M. S. *et al.*, 2003), procedural pain such as colonoscopy (Froehlich, F. *et al.*, 1997), and conditions presented in emergency rooms (Boccardi, L. and Verde, M., 2003). In addition, women display greater perceptual responses to laboratory-induced pain relative to men, although the magnitude of these differences varies across studies, perhaps due to methodological differences (e.g., pain assay, stimulus characteristics, sample selection; Fillingim, R. B. and Maixner, W., 1995; Riley, J. L. *et al.*, 1998). Interestingly, consistent with the human literature, greater behavioral responses to noxious stimuli have been reported among female compared to male rodents (e.g., Barrett, A. C. *et al.*, 2002b; 2003; Terner, J. M. *et al.*, 2003; also for reviews, see Bodnar, R. J. *et al.*, 1988; Berkley, K. J., 1997), with some exceptions (Mogil, J. S. *et al.*, 1993; Kayser, V. *et al.*, 1996). In general, these findings suggest that females exhibit greater perceptual responses to pain than males; however, the mechanisms underlying these sex differences have not been determined.

5.21.2 Sex Differences in Responses to Pain Treatment

In addition to basal pain sensitivity, sex-related influences on responses to pharmacologic and nonpharmacologic pain treatments have received

increasing attention in recent years. The rodent literature fairly consistently demonstrates greater analgesic responses to opioid agonists among males versus female animals (Bodnar, R. J. *et al.*, 1988; Kepler, K. L. *et al.*, 1989; 1991; Kiefel, J. M. and Bodnar. R. J., 1992; Islam, A. K. *et al.*, 1993; Cicero, T. J. *et al.*, 1996a; 1997; Kest, B. *et al.*, 2000; Craft, R. M., 2003a; 2003b). However, the human literature regarding sex differences in analgesic responses has shown mixed results. Some clinical studies demonstrate greater analgesic responses among women, others show no sex differences, and others report greater analgesia among men (Fillingim, R. B. and Gear, R. W., 2004). Among the most consistent findings is a series of studies indicating more robust analgesic responses κ-opioid-acting drugs after oral surgery (Gear, R. W. *et al.*, 1996a; 1996b; 1999; 2003). Laboratory studies in humans have shown mixed results, as well (Sarton, E. *et al.*, 2000; Fillingim, R. B. *et al.*, 2004; Romberg, R. *et al.*, 2004; Olofsen, E. *et al.*, 2005; Fillingim, R. B. *et al.*, 2005c). Sex differences in response to nonpharmacologic interventions for pain has received less empirical attention, though a few laboratory (Keogh, E. *et al.*, 2000; Sternberg, W. F. *et al.*, 2001) and clinical (Hansen, F. R. *et al.*, 1993; Krogstad, B. S. *et al.*, 1996; Jensen, I. B. *et al.*, 2001) studies suggest that sex differences in treatment responses may emerge. It is possible that the consistent sex differences in analgesic responses are specific to the oral surgery pain model, perhaps due to its inflammatory component or based on interactions with other medications administered perioperatively. The clinical relevance of these results beyond this acute pain model remains unknown, and this is an area ripe for future investigation.

5.21.3 Mechanisms Underlying Sex Differences in Pain

It is important to recognize that sex differences in pain are inevitably determined by interactions among multiple biopsychosocial processes. While these mechanisms are typically described as either psychosocial or biological, this dualistic conceptualization is artificial and potentially counterproductive. For instance, sex differences in expression of pain are often attributed to the effects of stereotypic sex roles, typically considered a psychosocial issue. However, neurobiological and hormonal correlates of masculine versus feminine sex roles may well contribute to differences in nociceptive processing. Thus, various psychosocial and biological mechanisms underlying sex differences in pain responses could refer to the same fundamental processes described at different levels of analysis.

Several biological variables have been implicated in sex differences in both clinical and experimental pain responses. Abundant preclinical and clinical evidence suggests that gonadal hormones are important, because hormonal influences on basal pain sensitivity as well as responses to analgesic compounds have been well documented (Riley, J. L. III. *et al.*, 1999; Fillingim, R. B. and Ness, T. J., 2000; Bodnar. R. J. *et al.*, 2002). Also, endogenous pain inhibitory systems may function differently in females and males, including the endogenous opioid system. Zubieta and colleagues have reported sex differences in both basal and pain-evoked μ-opioid receptor binding in certain brain regions (Zubieta, J. K. *et al.*, 1999; 2002). Genetic factors may also contribute to sex differences in pain. In rodents, sex differences in nociceptive and antinociceptive responses are often strain-dependent (Mogil, J. S. *et al.*, 2000; Barrett, A. C. *et al.*, 2002a; Terner, J. M. *et al.*, 2003), and pain-related quantitative trait loci (QTLs) are often sex-specific (Mogil, J. S. *et al.*, 1997; Mogil, J. S., 2000). Recent findings provide corroborating results in humans (Kim, H. *et al.*, 2004). Also, Mogil J. S. *et al.* (2003) demonstrated in both mice and humans that the melanocortin-1-receptor gene (*MC1R*) was associated with analgesic responses to κ-opioids among females but not males. Also, the A118G single nucleotide polymorphism of the μ-opioid receptor gene (*OPRM1*) was significantly associated with pressure pain thresholds, but this association was only significant among males (Fillingim, R. B. *et al.*, 2005b). Thus, several biological factors may contribute to sex differences in pain.

Numerous psychosocial variables also contribute to sex differences in pain responses. Anxiety and other negative emotions have been more strongly related with both clinical and experimental pain responses among men than women (Fillingim, R. B. *et al.*, 1996; Edwards, R. R. *et al.*, 2000; Riley, J. L., III *et al.*, 2001; Jones, A. and Zachariae, R., 2002; Robinson, M. E. *et al.*, 2005) Moreover, positive affect predicted lower experimental pain sensitivity and fewer side effects in responses to pentazocine (a mixed action opioid) among men, but not women (Fillingim, R. B. *et al.*, 2005a). Additional psychosocial factors that may contribute to sex differences in pain include cognitive and behavioral pain coping strategies (Affleck, G. *et al.*, 1999; Unruh, A. M. *et al.*, 1999; Keefe, F. J. *et al.*, 2000; Mercado, A. C. *et al.*, 2000; Osman, A. *et al.*, 2000), gender roles (Otto, M. W. and

Dougher, M. J., 1985; Myers, C. D. *et al.*, 2001; Robinson, M. E. *et al.*, 2003), and family history of pain (Edwards, P. W. *et al.*, 1985; Fillingim, R. B. *et al.*, 2000).

5.21.4 Conclusions and Future Directions

The evidence reviewed indicates consistent sex differences in pain-related responses, to which multiple biopsychosocial factors contribute. The literature focuses more heavily on quantitative sex differences (i.e., does the magnitude of pain or analgesia differ in women vs. men?); however, of equal if not greater importance are qualitative sex differences (i.e., are the mediators of pain and analgesia different in women vs. men?). Some examples are provided above, including findings demonstrating sex-specific genetic and psychosocial associations with pain. The clearest challenge for the future is to determine the practical significance of these sex differences and to integrate this information into clinical practice. It seems plausible that expanding research into qualitative sex differences may be more informative in this regard, because such differences imply that some components of the pain processing system may be fundamentally different in women versus men, which calls for sex-specific treatment approaches. It is hoped that continued research into sex, gender and pain will ultimately enhance pain management for both women and men.

Glossary

immunoadhesin A chimeric molecule consisting of a IgG backbone (Fc region) linked to the binding site of a receptor that binds to a molecule to be sequestered, e.g., trkA-IgG binds nerve growth factor (NGF).

keratinocyte Immune-competent cell in the epidermis.

mast cell Immune-competent cell that stores inflammatory mediators.

neutrophil A type of white blood cell that phagocytoses microorganisms (i.e., due to infection) and breaks them down.

skin nerve preparation *In vitro* preparation in which the skin is removed with its nerve supply (e.g., ankle skin and saphenous nerve) and placed in a chamber. The nerve is led into a second chamber separated from the skin chamber so that the skin can be maintained in oxygenated Ringer, whereas the nerve can be placed in oil for extracellular recording.

tachyphylaxis A process whereby the response to an agent applied repeatedly becomes smaller and smaller.

5.22.1 The Neurotrophin Family and Its Receptors

Neurotrophin molecules are 13.5-kDa proteins that come in four major forms that show a substantial overlap in their primary structure. These are known as nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4 (also known neurotrophin-5 or neurotrophin-4/5, NT-4/5). The molecular biology underlying the synthesis of these molecules has been reviewed elsewhere (Teng, K. K. and Hempstead, B. L., 2004). Neurotrophins bind to two classes of receptors: the tropomyosin-related kinase (trk) receptors, trkA, trkB, and trkC, as well as the p75 receptor that is a member of the tumor necrosis factor (TNF) superfamily. Although these two receptor types are often considered to function together as a complex (Chao, M. V. and Hempstead, B. L., 1995; He, X. L. and Garcia, K. C., 2004), there is also evidence that they can function independently (see Section 5.22.7).

The trk receptors are known as the high-affinity neurotrophin receptors and selectively bind the different neurotrophin molecules. NGF binds selectively to trkA, BDNF and NT-4/5 to trkB, and NT-3 to trkC (Huang, E. J. and Reichardt, L. F., 2001). Some cross-binding with lower affinity also occurs (Barbacid, M., 1994). The p75 receptor is generally known as the low-affinity receptor, although it actually binds neurotrophins with high affinity but with rapid kinetics. It binds all known neurotrophins with similar affinity. Thus, the selective expression of trk receptors in different cell types (MCMahon, S. B. *et al.*, 1994) is a major factor underlying the selective effects of neurotrophins in the nervous system.

Ligands binding to the extracellular component of trk receptors induce autophosphorylation of the trk molecule, which leads to downstream effects via multiple signaling pathways (Kaplan, D. R. and Miller, F. D., 2000). For example, phospholipase Cγ (PLCγ) is phosphorylated subsequent to its recruitment to the cell membrane as a consequence of phosphorylation of tyrosine 785 on trkA (Obermeier, A. *et al.*, 1993). This is very likely an important mechanism in mediating neurotrophin-induced effects (see below). However, other intracellular signaling pathways are also activated by neurotrophin binding to trk receptors including the Ras–Raf–Mek–Erk pathway and the PI-3K pathway (Kaplan, D. R. and Cooper, E., 2001). Some of these have also been implicated in mediating the functional effects of neurotrophins (see Section 5.22.6).

5.22.2 Neurotrophins and Development of Nociceptors

The early history of the discovery of NGF has been extensively reviewed (Cowan, W. M., 2001). It began with the observation that extracts from mouse salivary glands induce proliferation of processes of explanted dorsal root ganglion (DRG) and sympathetic ganglion cells. Later, biochemical studies revealed that the active factor is a peptide that became known as nerve growth factor. NGF was subsequently identified as an important factor assuring survival of developing sensory neurons since its absence induced by treating the animal with an NGF antibody resulted in the survival of fewer cells in the DRG as well as in sympathetic ganglia. This led to the neurotrophic hypothesis (Davies, A. M., 1996), which states that a soluble trophic factor is present in limiting amounts in the target tissue of a population of neurons, which require it in order to survive. Nerve terminals that are successful in internalizing this factor and transporting it to the cell body for its metabolic use survive; the unsuccessful ones die. More detailed studies of the DRG revealed that selective neutralization of NGF via its antibody results in depletion of a limited population of DRG cells, specifically those that express peptides such as substance P and calcitonin gene-related peptide (CGRP) and project into superficial laminae of the spinal cord. i.e., those that are identified with nociception (reviewed in Mendell, L. M., 1995). Animals treated in this way exhibit a higher threshold for painful stimuli. Genetically modified animals have proven very useful in demonstrating these relationships with those under- or overexpressing NGF in the skin being hypo- or hyperalgesic, respectively (Davis, B. M. *et al.*, 1993), and those underexpressing the NGF receptor trkA being hypoalgesic (Smeyne, R. J. *et al.*, 1994).

In all these manipulations, NGF was considered to affect the number of nociceptors, permitting more or fewer to survive. However, it has become apparent that NGF influences the properties of nociceptors in the immediate postnatal period, beyond the time it can affect DRG cell number. Ritter A. M. *et al.* (1991; see also Lewin, G. R. *et al.*, 1992a) demonstrated that a class of nociceptors known as Aδ high-threshold mechanoreceptors (HTMRs) is severely depleted in rats treated postnatally with an antibody to NGF (anti-NGF). The proportion of Aδ low-threshold mechanoreceptors known as down hair receptors (D hairs) is elevated by a similar proportion.

Significantly, the proportion of a third population of afferent fibers also conducting in the Aδ range and innervating subcutaneous tissues is unchanged. Thus, HTMRs are not selectively depleted since if this occurs, the proportion of all other fiber types would be expected to increase. Furthermore, when cell counts were undertaken in the DRG, no change in cell number was noted. Consistent with these findings, the magnitude of the vasodilator response elicited by antidromic activation of cutaneous nerves is reduced in proportion to the depletion of Aδ HTMRs (Lewin, G. R. *et al.*, 1992b).

These findings suggest that the postnatal development of nociceptors depends on the availability of NGF and that in its absence sensory neurons normally destined to be HTMRs become D hairs. This has been referred to as a phenotypic shift (Lewin, G. R. *et al.*, 1992a). Cell number in the DRG declines if the antibody is delivered between P0 and P2, whereas the phenotypic shift from HTMR to D hair occurs after anti-NGF treatment between P4 and P11. Attention was drawn to evidence that sensory axons normally first innervate the epidermis, with many terminals later withdrawing to the dermal layer as hair follicles and other structures develop (Reynolds, M. L. *et al.*, 1991). NGF is expressed by a limited population of cells in the epidermis, for example in basal keratinocytes (Di Marco, E. *et al.*, 1991), and it was hypothesized that the availability of NGF there would cause trkA-expressing neurons to differentiate into nociceptors with epidermal terminals. In the absence of NGF due to anti-NGF treatment, these terminals would recede into the dermal layers of the skin, as occurred with most non-trkA-expressing neurons (reviewed in Lewin, G. R. and Mendell L. M., 1993; Mendell, L. M. *et al.*, 1999).

Exogenous NGF delivered postnatally does not elevate the relative proportion of HTMRs (Lewin, G. R. *et al.*, 1993). However, enhancing NGF levels in the skin beginning during development (E11) in transgenic mice via the keratin promoter increases the number of sensory neurons well above normal levels (Albers, K. M. *et al.*, 1994). Electrophysiological studies have confirmed that nociceptors are selectively rescued by the availability of the additional NGF (Stucky, C. L. *et al.*, 1999).

The DRG cell population undergoes substantial changes in the expression of trkA postnatally. A substantial number lose trkA expression over the first 3 postnatal weeks, and there is a parallel increase in the number of cells exhibiting receptors for glial-derived neurotrophic factor (GDNF) (Molliver, D. C. *et al.*, 1997). Cells undergoing this conversion do not express p75 even in neonates, i.e., they are $p75^{-}/trkA^{+}$ as distinct from cells that are $p75^{+}/trkA^{+}$ (Figure 1). Receptors for GDNF consist of an intracellular signaling receptor domain RET, which is a tyrosine kinase receptor. There are four different ligand-binding domains, GFR1–GFR4, that bind different members of the GDNF family. GDNF itself binds to GFRα1. Other agonists are neurturin (NTN) binding to GFRα2, artemin binding to GFRα3 and persepherin that binds to GFRα4 (Saarma, M.

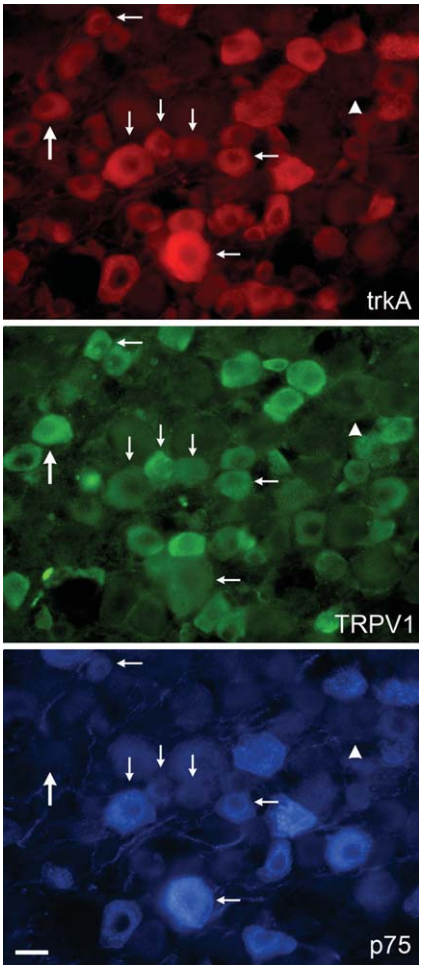

Figure 1 Dorsal root ganglion (DRG) tissue section from 10-day-old rat immunostained for trkA (red), TRPV1 (green), and p75 (blue). Most small cells are at least weakly positive for trkA, TRPV1, and p75 (small down and horizontal arrows). In one case (large up arrow), the cell was $trkA^{+}/TRPV1^{+}/p75^{-}$; this cell was likely to lose its trkA expression and gain receptors for GDNF. The cell denoted by an arrowhead is negative for all three markers used. Scale bar (*lower left*) is 20 μm. Data from Petruska J. C. and Mendell L. M. (unpublished).

and Sariola, H., 1999). In rats, the population expressing cRet also express the lectin IB4 (in adults $trkA^+$ cells are $IB4^-$). In mice, this separation is not as distinct. In rats, $IB4^+/cret^+/trkA^-$ cells have been shown to project more deeply into lamina II (lamina IIi) and are considered to be sensitive to nonnoxious stimulation. These neurons, unlike $trkA^+/IB4^-$ neurons, do not contain CGRP. GDNF has actions on GFR/Ret-expressing nociceptors that only partially overlap those of NGF on trkA-expressing nociceptors (see Section 5.22.8).

5.22.3 Nerve Growth Factor Affects Electrophysiological Properties of Nociceptors that Express TrkA

The finding that treatment with anti-NGF affects properties of nociceptors suggested that trkA is expressed selectively in nociceptors. This has been confirmed in a number of electrophysiological studies (Ritter, A. M. and Mendell, L. M., 1992; Djouhri, L. *et al.*, 2001) where application of NGF or anti-NGF was found to affect properties of the action potential in nociceptors only, regardless of axon size (Aβ, Aδ, or C). Interestingly, both these studies found effects on action potential fall time although the effects differed, probably because of the very different conditions of the experiments. Both studies also revealed that NGF does not affect the duration of after hyperpolarization. The selective expression of trkA in electrophysiologically characterized nociceptors has recently been confirmed directly by Fang X. *et al.* (2005).

5.22.4 Exogenous Nerve Growth Factor Elicits Hyperalgesia

5.22.4.1 Chronic Changes

Neonatal rats are more sensitive to being handled after an initial injection of NGF (Lewin, G. R. *et al.*, 1993). It was surmised that changes had occurred in the nociceptive system. Behavioral studies in 5-week-old rats treated with NGF every other day from birth revealed both mechanical and thermal hyperalgesia (Lewin, G. R. *et al.*, 1993). Additional studies with serial observations on rats treated either as neonates (0–2 weeks old) or as juveniles (2–5 weeks old) demonstrated that the sensitizing effect of NGF lasts several weeks after the end of treatment.

Individual Aδ HTMRs in rats treated systemically over the first 2 postnatal weeks with NGF exhibit a significantly diminished mechanical threshold (i.e., are more sensitive) up to 9 weeks of age after which it returns to control values (Lewin, G. R. *et al.*, 1993). Neonatal treatment with anti-NGF elevates mechanical threshold (Lewin, G. R. *et al.*, 1992). Treatment of older rats with NGF has no measurable effect on mechanical threshold. A similar study on C-fibers (Lewin, G. R. and Mendell, L. M., 1994) has revealed that treatment with NGF increases the fraction sensitive to noxious heat, whereas anti-NGF reduces it. Unlike the changes in mechanical sensitivity in Aδ-fibers, these changes are apparently permanent. The mechanical sensitivity of these C-fiber units is unchanged, although a population of mechanically sensitive units with an unusually low threshold is observed in anti-NGF-treated preparations. Reducing NGF levels in the skin in adult rats using the immunoadhesin trkA-IgG 10–12 days before recording (Bennett, D. L. *et al.*, 1998a) also causes a substantial decline in the response of individual units to noxious heat with no change in the response to mechanical stimulation. The number of units sensitive to bradykinin also decreases after trkA-IgG treatment, suggesting an important contribution of NGF to bradykinin sensitivity of nociceptors (see Section 5.22.8.4).

5.22.4.2 Acute Changes

Examination of the acute effects of a single administration of NGF (i.p.) in adult rats revealed that thermal hyperalgesia becomes significant virtually immediately, unlike mechanical hyperalgesia that develops gradually and reaches significance only after a few hours. Hyperalgesia elicited by a single i.p. injection of NGF lasts several days. Localized small injections of NGF into the skin elicit thermal and mechanical hyperalgesia of much shorter duration (Woolf, C. J. *et al.*, 1994; Shu, X. *et al.*, 1999). These local injections indicate the likelihood that NGF can act directly on cells located in the skin. NGF itself does not evoke any behavioral response; it merely sensitizes the response to subsequent nociceptive stimuli.

Although administration of NGF to the skin elicits hyperalgesia, it does not cause inflammation. On the other hand, treatments or injuries that elicit inflammation, such as complete Freund's adjuvant (CFA), enhance NGF levels in the skin (Weskamp, G. and Otten, U., 1987; Aloe, L. *et al.*, 1992).

Inflammatory cytokines, specifically TNFα and IL-1β, known to be expressed during inflammation, enhance NGF levels when delivered separately into the skin (Woolf, C. J. *et al.*, 1997). These studies have suggested a temporal sequence: TNF$\alpha \rightarrow$ IL-1$\beta \rightarrow$ NGF (Figure 2). Cells responsible for producing NGF include keratinocytes (Di Marco, E. *et al.*, 1991) and mast cells (Leon, A. *et al.*, 1994).

The requirement for NGF as an essential intermediate in causing inflammatory hyperalgesia has been demonstrated in experiments where its levels are experimentally diminished using an antibody to NGF (Lewin, G. R. *et al.*, 1994; Woolf, C. J. *et al.*, 1994) or an immunoadhesin such as trkA-IgG (McMahon, S. B. *et al.*, 1995; Koltzenburg, M. *et al.*, 1999), both of which deplete endogenous NGF. These agents prevent the development of hyperalgesia to mechanical or thermal stimuli in response to inflammatory agents such as CFA. In the case of thermal hyperalgesia, these agents can also substantially reduce ongoing inflammatory pain within an hour. However, mechanical hyperalgesia is reduced only after 24–48 h (Woolf, C. J. *et al.*, 1994; 1996). This difference between thermal and mechanical hyperalgesia is consistent with the conclusion, based on the latency of onset after exposure to NGF, that thermal hyperalgesia is due to a peripheral action, whereas the mechanical hyperalgesia is indirect, probably involving transcriptional changes at the level of the DRG (but see Section 5.22.7).

Rueff A. and Mendell L. M. (1996) recorded the activity of single nociceptor axons in an excised skin nerve preparation with the corium side up where NGF could be applied directly to the electrophysiologically identified receptive field of the fiber. They tested the response to noxious heat and mechanical stimulation under control conditions and 10 min later with NGF applied to the corium surface of the unit or under control conditions (no NGF). They observed a significant decline in threshold to noxious heat, but no acute change in threshold to mechanical stimulation. The sensitivity to NGF was abolished if mast cells were degranulated over a period of several days prior to treatment (see Section 5.22.4.3).

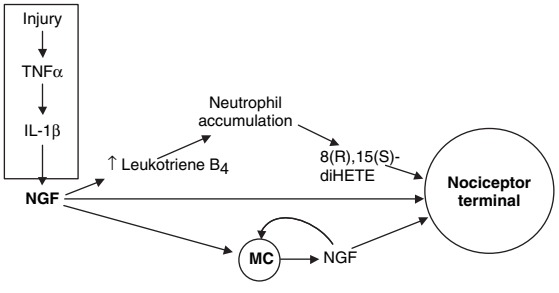

Figure 2 Major mechanisms underlying acute action of nerve growth factor (NGF) on sensory neurons. Exogenous NGF sensitizes sensory neurons via neutrophils, mast cells (MCs), and perhaps directly. Other possible mechanisms are mentioned in the text. NGF is released endogenously after injury via the action of cytokines TNFα and IL-1β (rectangle).

5.22.4.3 Mechanisms of Nerve Growth Factor Action in the Skin

A number of pharmacological approaches have been undertaken to explore the identity of cells and mechanisms underlying sensitization of nociceptive responses by NGF. A contribution by the sympathetic nervous system to the sensitizing effect of NGF has been identified since guanethidine treatment substantially reduces NGF's acute hyperalgesic effect (Andreev, N. Yu. *et al.*, 1995) by delaying its onset (Woolf, C. J. *et al.*, 1996).

Mast cells also participate in NGF-induced sensitization, particularly of noxious thermal stimuli. Mast cells express trkA receptors (Horigome, K. *et al.*, 1993), and NGF causes them to degranulate their contents consisting of serotonin, histamine, and NGF itself (reviewed in Mendell, L. M. *et al.*, 1999). Degranulation of mast cells in advance of NGF administration delays the development of thermal hyperalgesia for about 3 h but does not prevent the later phase of thermal hyperalgesia, nor does it abolish mechanical hyperalgesia (Lewin, G. R. *et al.*, 1994; see also Woolf, C. J. *et al.*, 1996). Behavioral experiments using pharmacological antagonists indicate that serotonin is an important contributor to mast cell-mediated sensitization initiated by NGF (Lewin, G. R. *et al.*, 1994). Under some special conditions, NGF can elicit sensitization in the absence of mast cell activity (Amann, R. *et al.*, 1996a), suggesting the existence of other pathways (Figure 2), or perhaps that NGF acts directly on trkA receptors expressed by other cells, for example, the nociceptors themselves (Averill, S. *et al.*, 1995; Galoyan, S. M. *et al.*, 2003; see Section 5.22.5).

Another action of NGF is enhancement of the level of leukotrienes, specifically leukotriene B_4 (LTB_4), via upregulation of the enzyme 5-lipoxygenase (Amann, R. *et al.*, 1996b; Bennett, G. *et al.*, 1998b). Leukotrienes are known to sensitize nociceptors (Martin, H. A. *et al.*, 1988). This occurs as a result of neutrophil accumulation and their subsequent

release of 8(R), 15(S)-diHETE. If neutrophils are depleted pharmacologically, NGF-induced hyperalgesia is abolished (Bennett, G. *et al.*, 1998b).

Keratinocytes may also play an important role in NGF-induced hyperalgesia. These cells are known to express trkA receptors and to contain NGF (Terenghi, G. *et al.*, 1997) and thus may act in a manner similar to that described for mast cells (see above). They are also known to release ATP (Koizumi, S. *et al.*, 2004) that activates nociceptor terminals (Cook, S. P. and McCleskey, E. W., 2002). Enhancement of NGF expression in these cells in genetically modified mice enhances nociceptive behavior (Davis, B. M. *et al.*, 1993).

The multiplicity of cell types that express trkA receptors and the number of substances capable of sensitizing nociceptors released by these cells in response to NGF indicate the complexity of peripheral sensitization by neurotrophins. They also indicate the difficulty of using behavioral methods and preparations such as the skin nerve preparation, where all these cells remain in close contiguity, to arrive at cellular mechanisms of sensitization. Thus, many studies have made use of dissociated DRG cells to examine the effects of NGF directly on trkA-expressing neurons. Such studies have the obvious advantage of providing a relatively unobstructed view of cellular mechanisms but at the expense of the intercellular interactions that take place *in vivo*.

5.22.5 Acute Sensitization by Nerve Growth Factor of the Response of Dissociated Nociceptors

Shu X. Q. and Mendell L. M. (1999a; 1999b) have investigated the effect of NGF on the response of small (<30 μm) dissociated DRG cells to capsaicin, known to elicit the sensation of noxious heat (Lamotte, R. H. *et al.*, 1992) via the VR1 (now referred to as TRPV1) receptor (Caterina, M. J. *et al.*, 1997). NGF sensitizes the response to capsaicin (Shu, X. and Mendell, L. M., 1999b), measured as an increased inward current in the presence of NGF, in a dose-dependent manner over the range of 2–100 ng ml^{-1}. Its effect is blocked by the protein kinase inhibitor K252a known to antagonize the response of trkA, although not in a highly selective manner (Knusel, B. and Hefti, F., 1992). Not all cells tested are sensitized by NGF, indicating that not all these small cells express the trkA receptor, as predicted from immunohistochemical studies (Averill, S. *et al.*, 1995; Bennett, D. L. *et al.*, 1996a; Figures 1 and 3).

The duration of NGF action is difficult to determine because the test input, capsaicin, is associated with long-lasting tachyphylaxis. To circumvent this problem, Shu X. and Mendell L. M. (2001) have examined the duration of NGF action under conditions of reduced Ca^{2+} that eliminates tachyphylaxis

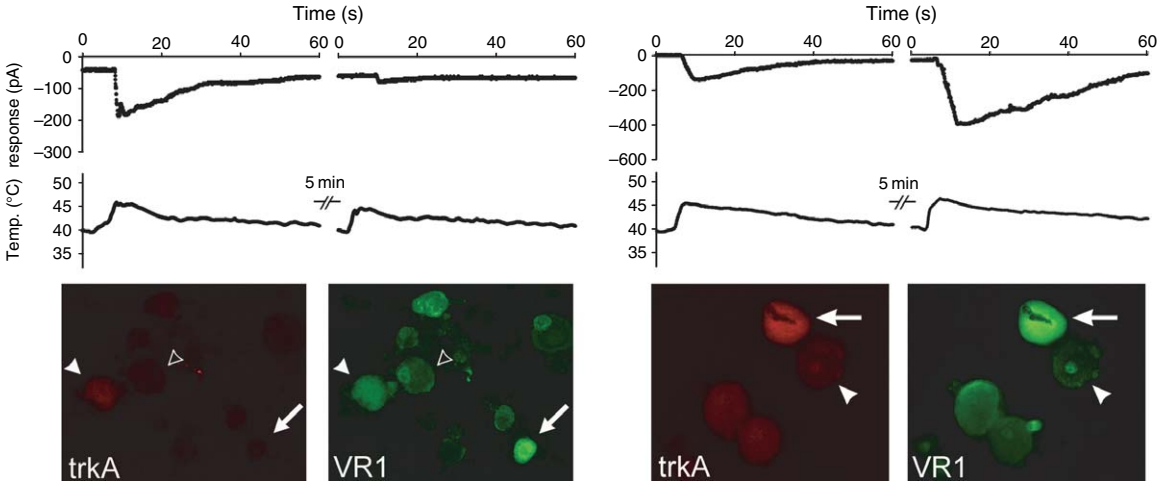

Figure 3 The response of two dissociated dorsal root ganglion (DRG) cells to administration of nerve growth factor (NGF) and demonstration that sensitization of the response requires expression of trkA. Cell on left was tested with two heat pulses (*bottom traces*). The second response 5 min later exhibited tachyphylaxis despite the presence of NGF in the bathing solution for 5 min between heat pulses. The cell (diameter 26 μm; thick arrow) was recovered and immunostained for TRPV1 and trkA. It was classified as $TRPV1^{+}/trkA^{-}$. Another cell in the same field denoted by white arrowhead is $trkA^{+}/TRPV1^{+}$ and a third cell denoted by white-bordered arrowhead is classified $trkA^{-}/TRPV1^{-}$. Cell on right showed sensitization of the response to heat after 5 min exposure to NGF. The cell (diameter 25 μm; arrow) was recovered, immunostained, and classified $trkA^{+}/TRPV1^{+}$. Cell denoted by arrowhead was $trkA^{-}/TRPV1^{-}$. Adapted from Galoyan *et al.* (2003) with permission.

(Koplas, P. A. *et al.*, 1997). They found that a 10-min exposure to NGF sensitizes a neuron to repeated puffs of capsaicin for as long as 70 min, suggesting that the effect of NGF involves more than a direct action on the conductance of a membrane channel or the sensitivity of a receptor (see Section 5.22.6).

Galoyan S. M. *et al.* (2003) have carried out similar experiments in small dissociated DRG cells from adult rats using noxious heat instead of capsaicin as the test stimulus (Figure 3). One advantage of the noxious heat stimulus over capsaicin is the ease with which threshold can be established. These cells respond an inward current whose threshold is 43–44 °C which is characteristic of the TRPV1 receptor expressed in hetrologous cells (caterina, M. J., *et al.*, 1997). NGF-induced sensitization of the response to noxious heat has properties that are similar to sensitization of the response to capsaicin. NGF does not alter temperature threshold; its major effect is to enhance the magnitude of the heat evoked current. Recent studies suggest that the acute increase of TRPV1 current elicited by exposure to NGF is due to increased trafficking and subsequent insertion of the additional TRPV1 receptors into the plasma membrane rather than an increase in channel unitary conductance (Zhang, X., *et al.*, 2005; Stein, A. T., *et al.*, 2006). These cells respond with a threshold of about 43–44 °C, which is characteristic of the TRPV1 receptor (Caterina, M. J. *et al.*, 1997). NGF-induced sensitization of the response to noxious heat has properties that are similar to sensitization of the response to capsaicin. One of the advantages of noxious heat over capsaicin as the stimulus is the ability to establish a threshold value. This has permitted the conclusion that NGF does not alter temperature threshold; its major effect is to enhance the magnitude of the heat-evoked current.

As observed with capsaicin, NGF does not sensitize the heat-evoked response in some neurons. Immunohistochemical characterization of the recorded cells has revealed that the NGF-induced sensitization of the heat-evoked inward current is closely associated with the expression of trkA (Figure 3). This is not unexpected since studies in heterologous cells have demonstrated that the ability for NGF to sensitize the TRPV1 response requires that the cell express trkA (Chuang, H. H. *et al.*, 2001).

Zhu W. *et al.* (2004) have recently demonstrated that the capsaicin- or noxious heat-induced TRPV1 response in DRG cells isolated from neonatal rats cannot be sensitized by NGF unlike the response in cells from adults. Thus, in neonates, there is no close correspondence between the expression of trkA and the ability of NGF to sensitize the TRPV1 response, i.e., trkA is expressed in cells that fail to be sensitized by NGF. However, cells in neonates failing to be sensitized by NGF can be sensitized by bradykinin, i.e., the failure for NGF to sensitize the cells is not a generalized failure for sensitization to occur. It is not presently known what factor develops during the neonatal period that permits NGF to sensitize the heat-evoked response.

NGF-induced sensitization develops gradually from P4 to P10 (Zhu, W. *et al.*, 2004). This is the time at which trkA-expressing cells lose their requirement for NGF in order to survive (Lewin, G. R. *et al.*, 1992). It has been hypothesized that the inability for NGF to sensitize cells in neonates may be a protective mechanism to prevent undue nociceptive input due to sensitization at a time that NGF is required to assure survival of nociceptors (Zhu, W. *et al.*, 2004).

GDNF, like NGF, acutely elevates cytosolic Ca^{2+} in DRG cells (Lamb, K. and Bielefeldt, K., 2003). Recent experiments suggest that exposure of dissociated sensory neurons to GDNF, neurturin or artermin for several minutes rapidly enhances the sensitivity of TRPV1 receptors to capsaicin in isolated DRG cells (Malin, S. A., *et al.*, 2006). Artemin mRNA, but not neurturin or GDNF, is upregulated in the skin in response to inflammatory conditions; its expression increases faster, and to a greater extent, than that of NGF. Administration of these agents elicits thermal hyperalgesia lasting several hours which is substantially prolonged if NGF is co-injected. These findings broaden our understanding of the role of trophic factors in sensitization of nociceptors.

5.22.6 TrkA Signaling Pathways Responsible for Acute Effects of Nerve Growth Factor

Signaling initiated by trk receptor activation is diverse, and for a general treatment of this subject from a more molecular perspective, the reader is referred to a recent review (e.g., Huang, E. J. and Reichardt, L. F., 2001; Nicol, G. D. and Vasko, M. R., 2007). Many studies carried out on NGF-induced signaling have been directed toward determining the signaling pathways involved in cell survival and axon outgrowth. Here, we provide a more focused

treatment related to NGF's role as a sensitizing agent in sensory neurons.

Chuang H. H. *et al.* (2001) reported that phosphatidyl-4.5-inositol biphosphate (PtdIns(4,5)P_2 – PIP_2) exerts a tonic inhibitory effect on the inward current produced by TRPV1 via its interaction with the C-terminal domain of TRPV1. They suggested that NGF sensitizes TRPV1 by activating PLC which inhibits PIP_2, thereby disinhibiting TRPV1, a mechanism corroborated by the demonstration that the PLC inhibitor U-73122 antagonizes the sensitizing effect of NGF in adult rat DRG neurons (Galoyan, S. M., *et al.*, 2003). This mechanism has not been confirmed in subsequent studies (see below). Furthermore, recent findings suggest that PIP_2 facilitates rather than inhibits TRPV1 receptor activity (Stein, A. T. *et al.*, 2006). A related finding indicates that PIP_2 is required for recovery from desensitization (Lin, B., *et al.*, 2005) known to occur after TRPV1 receptor activation.

Chuang H. H. and coworkers pointed out that the activation of PLC would also be expected to enhance levels of protein kinase C (PKC) via diacylglycerol (DAG). However, they found that inhibitors of PKC fail to abolish NGF-induced sensitization of TRPV1. This has been confirmed by Shu X. and Mendell L. M. (2001) in adult rat DRG cells using a different pair of PKC blockers. Interestingly, other investigators working in dissociated DRG neurons have obtained very different results on the signaling pathways involved in NGF-induced sensitization. Bonnington J. K. and McNaughton P. A. (2003), working in neonatal mouse DRG cells, used a different inhibitor of PLC, neomycin, and found no inhibition of NGF-induced sensitization of the capsaicin response and also that the most robust inhibition of NGF-induced potentiation occurred by blocking the activity of PI-3K and PKC, the latter in contrast to the earlier findings (see above). Zhuang Z.-Y. *et al.* (2004), working in adult rat (see also Zhu, W. and Oxford, G. S., 2007) have confirmed the role for PI-3K in NGF-induced sensitization, agreeing with Bonnington J. K. and McNaughton P. A., but also reported that the MEK inhibitor PD98059 blocked the effect of NGF unlike the findings of both Bonnington J. K. and McNaughton P. A. (2003) and Shu X. and Mendell L. M. (2001).

It is important to note that there are several differences among these experiments including the use of rats and mice of different strains, cell culture conditions, protocols (e.g., number of capsaicin pulses), different assays such as Ca^{2+} imaging, and membrane current. These studies point out the complexity of studies on signaling pathways, specifically the need to define the conditions under which they are investigated. It may be necessary to carry out such studies *in vivo* where conditions are more tightly regulated in order to understand which of the many possible pathways are operating under physiological conditions.

5.22.7 p75 Receptor Influence on Sensory Neuron Function

The p75 receptor is expressed in all cells that also express trkA and trkB receptors, but in only about half the cells expressing trkC. Cells not expressing trk do not express p75 (Wright, D. E. and Snider, W. D., 1995). p75 binds all neurotrophins (see reviews by Patapoutian, A. and Reichardt, L. F., 2001; Huang, E. J. and Reichardt, L. F., 2001). The functional role of trk and p75 in mediating the effects of neurotrophins has received greatest attention in developmental studies as determinants of neuronal survival and apoptosis (Hempstead, B. L. *et al.*, 1991; Miller, F. D. and Kaplan, D. R., 2001). For example, p75 acts as a mediator of sympathetic neuron apoptosis, whereas trkA mediates cell survival (Majdan, M. *et al.*, 2001).

Relatively little attention was paid to the p75 receptor initially in evaluating the physiological effects of NGF because of evidence that sensitization to noxious heat by NGF is normal in p75 knockouts (Bergmann, I. *et al.*, 1998, but see von Schack, D. *et al.*, 2001, for evidence that this knockout is not complete). However, the finding that activation of p75 enhances ceramide via activation of the sphingomyelin pathway (Dobrowsky, R. T. *et al.*, 1994) prompted a search for physiological effects elicited by NGF binding to the p75 receptor (reviewed by Nicol, G. D. and Vasko, M. R., 2007). Zhang Y. H. *et al.* (2002) reported that NGF-induced activation of the ceramide pathway via the p75 receptor enhances membrane excitability (membrane gain-number of APs per nanoampere of current applied across the cell membrane) in capsaicin-sensitive DRG neurons (presumptive nociceptors) by enhancing a TTX-insensitive Na^+ conductance and decreasing the magnitude of the K^+-rectifier. These experiments were carried out first by short circuiting p75 by administering ceramide itself, and second by demonstrating that the effects of NGF could be blocked by administering glutathione, an inhibitor of neutral sphingomyelinase, the enzyme responsible for

producing ceramide (Liu, B. and Hannun, Y. A., 1997). A p75 blocking antibody also prevents ceramide facilitation of membrane gain (Zhang, Y. H. and Nicol, G. D., 2004). Thus, NGF might sensitize the response of the cell by enhancing its depolarization (trkA) and independently by increasing the number of action potentials produced per unit of depolarization (p75) (Mendell, L. M., 2002). In this context, it is interesting that one of the major deficits in p75-knockout mice is a substantial reduction of discharge frequency of certain mechanoreceptors (Stucky, C. L. and Koltzenburg, M., 1997).

Cellular mechanisms for interaction between p75 and trkA have also been described. Working in human neuroblastoma cells, Plo I. *et al.* (2004) reported that activation of trkA reduces sphingomyelinase levels and thus reduces ceramide production (i.e., reduced p75 signaling) via PKC. Similarly, Bilderback T. R. *et al.* (2001) demonstrated in PC12 cells that PI-3K, activated by NGF via trkA, acutely inhibits acidic sphingomyelinase activated by NGF via the p75 receptor. Since PI-3K under certain conditions has also been shown to play a role in NGF-induced activation of TRPV1 via trkA (see Section 5.22.6), NGF appears to have the potential to affect cell discharge in a complex manner involving interaction of the signaling pathways activated by p75 and trkA. Also in PC12 cells, MacPhee I. and Barker P. A. (1997; 1999) demonstrated a reciprocal action of NGF, i.e., brief activation of p75 acutely reduces trkA activity via a ceramide-dependent mechanism, whereas extended p75 activation facilitates trkA. Another recent report (He, X. L. and Garcia, K. C., 2004) suggests that NGF can bind to p75 in a 2:1 molecular ratio and that this complex might bind to trkA. Such a scheme would predict cooperativity between p75 and trkA at the level of the cell surface in addition to intracellular signaling. Furthermore, there is now evidence that p75 can modulate the action of the trk receptors by increasing trk receptor autophosphorylation (Berg, M. M. *et al.*, 1991; Verdi, J. M. *et al.*, 1994), by increasing the concentration of the neurotrophin in the vicinity of its trk receptor (Barker, P. A. and Shooter, E. M., 1994), and/or by increasing the selectivity of the trk receptor for its ligand (Rodriguez-Tebar, A. *et al.*, 1992; Benedetti, M. *et al.*, 1993). Thus, even though there is evidence for independent effects of neurotrophins via trkA and p75, the possibility that these pathways could interact in nociceptive neurons must be considered.

5.22.8 Effects of Nerve Growth Factor on Expression of Channels and Receptors in Nociceptors

The acute changes in sensory neuron function considered heretofore are very rapid and hence considered to be posttranscriptional changes. However, there is now substantial evidence that NGF can also regulate the expression of numerous receptors and channels via transcriptional mechanisms and in this way exert much more profound and long-lasting effects on the properties of nociceptors (Figure 4). Furthermore, in the case of several of the channels (TRPV1, BK, P2X3, and TTX-resistant Na^+ channels), there is evidence for differential regulation by NGF and GDNF.

5.22.8.1 TRPV1 Receptors

Chronic exposure of DRG cells in culture to NGF increases their response to capsaicin (Bevan, S. and Winter, J., 1995; Ganju, P. *et al.*, 1998); this is attributed to an increase in expression of TRPV1 associated with enhanced levels of TRPV1 mRNA (Winston, J. *et al.*, 2001). *In vivo* studies have documented that peripheral administration of NGF enhances expression of TRPV1 via activation of p^{38} MAP kinase in trkA+ sensory neurons in the DRG and in sciatic nerve and especially in the skin by selective centrifugal transport (Ji, R. R. *et al.*, 2002). A recent report (Amaya, F. *et al.*, 2004) has shown that the elevated expression of TRPV1 begins 1 day after CFA administration into the paw and lasts for up to 1 week, returning to normal at 2 weeks. Both NGF and GDNF levels increase in DRG neurons after CFA treatment, with NGF

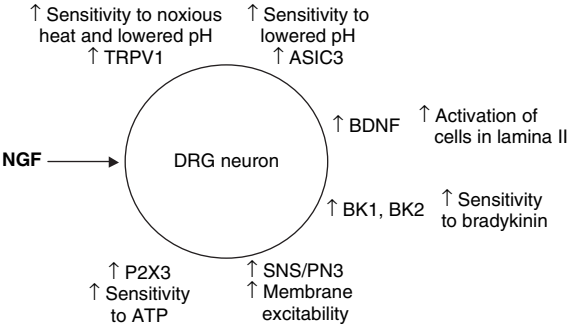

Figure 4 The variety of possible long-term actions of nerve growth factor (NGF) on expression of various channels, receptors, and neurotrophins in nociceptors. In each case, the major functional effect is listed. Further details in text.

exhibiting a relatively rapid rise and fall (peak at 1 day) and GDNF reaching its peak level at 1 week and falling to control levels by the second week. Selectively interfering with NGF and GDNF upregulation using antibodies has clarified that NGF and GDNF elevate TRPV1 expression in different populations of nociceptive sensory neurons, $trkA^+$ and $IB4^+$ neurons, respectively. Furthermore, restricting elevation of TRPV1 expression to either population of DRG cells reduces the thermal nociception elicited during CFA-induced inflammation.

5.22.8.2 P2X3 Receptors

NGF also enhances expression of the P2X3 receptor (Bradbury, E. J. *et al.*, 1998; Ramer, M. S. *et al.*, 2001) considered important in pain produced by ATP (Cook, S. P. and McCleskey, E. W., 2002). One week after intrathecal administration, GDNF elevates P2X3 expression in spinal terminals of Ret/$IB4^+$ neurons in which it is normally expressed. NGF has a more profound effect since it causes novel expression of P2X3 in neurons terminating in more superficial laminae of the spinal cord where P2X3 is normally not expressed. Although these latter changes are relatively small, it was concluded that they might be a significant component in NGF-mediated inflammatory pain.

5.22.8.3 ASIC Channels

ASIC channels are Na channels gated by H^+. The ASIC3 isoform is expressed in DRG cells identified as nociceptors by coexpression of markers characteristic of such neurons. Along with TRPV1 receptors, ASIC3 receptors are considered to be important mediators of the pain associated with tissue acidosis (Voilley, N. *et al.*, 2001). Mamet J. *et al.* (2003) have shown in culture that NGF enhances the expression of the ASIC3 isoform in DRG cells. They describe a physiological control mechanism, suggesting that low levels of NGF regulate ASIC3 expression via trkA and the PLC/PKC signaling pathway. During inflammation, NGF levels rise and the increased activation of p75 removes inhibition of the downstream effects of JNK and p38 that are also activated by NGF via trkA (Ji, R. R. *et al.*, 2002). Since these downstream effects include expression of ASIC3, this mechanism can act as a switch whereby the enhanced level of NGF switches on production of ASIC3 by removing tonic inhibition of JNK and p38.

5.22.8.4 BK Receptors

Another receptor upregulated by NGF is a member of the bradykinin (BK) receptor family. Nociceptors express the B2 form of the BK receptor constitutively; the B1 form is expressed only after inflammation (Dray, A. and Perkins, M., 1993). McNaughton P. A. and coworkers have reported that freshly dissociated mouse DRG cells undergo upregulation of B2 mRNA (confirmed at the protein level immunocytochemically) when exposed to NGF for 3 days; GDNF is much less effective (Lee, Y. J. *et al.*, 2002). These studies are consistent with previous observations that cultured cells are more responsive to bradykinin when cultured in the presence of NGF (Petersen, M. *et al.*, 1998). The identity of the receptor responsible for this action of NGF (trkA or p75) is controversial (see discussion in Lee, Y. J. *et al.*, 2002). Interestingly, expression of the B1 receptor can be enhanced in cultured DRG neurons in the presence of GDNF but not NGF (Vellani, V. *et al.*, 2004). However, *in vivo* the effects of NGF may be much more complex as suggested by Rueff A. *et al.* (1996) who hypothesized that NGF might indirectly cause upregulation of B1 receptors on DRG neurons via release of cytokines such as TNFα and IL-1β from inflammatory cells.

5.22.8.5 Na^+ Channels

Waxman, S. G., Kocsis, J. D., and coworkers have shown that NGF can affect Na^+ and K^+ channel expression of nociceptive afferent fibers (Fjell, J. *et al.*, 1999; Everill, B. and Kocsis, J. D., 2000). Fjell J. and coworkers noted changes in the properties of small-diameter DRG cells after peripheral axotomy that could be reversed by administration of NGF. Specifically, they observed that axotomy diminishes the TTX-resistant Na current in these neurons and that provision of NGF partially reverses this decline due to an effect on SNS/PN3 TTX-resistant Na^+ channel (Na_v 1.8). NGF is unable to reverse the axotomy-induced attenuation of activity in NaN, another TTX-resistant Na^+ channel (Na_v 1.9). However, GDNF is able to reverse the decline in both NaN and SNS/PN3. Interestingly, GDNF but not NGF enhances TTX-resistant currents in small DRG neurons studied in culture, suggesting that the ability to restore function after axotomy does not predict effects under all conditions. However, given the likely importance of TTX-resistant Na^+ channels in the function of nociceptors (Ritter, A. M. and

Mendell, L. M., 1992; Fang, X. *et al.*, 2005), the finding that neurotrophins can influence their function makes this system a potentially important target in achieving pain control.

5.22.8.6 PGE2 Receptors

The multiplicity of channels affected by NGF suggests that this growth factor acts as a master switch in regulating the sensitivity of sensory neurons to nociceptive stimuli. However, its control is not universal since NGF does not control expression of the PGE2 receptor (Southall, M. D. and Vasko, M. R., 2000) that mediates the hyperalgesia caused by prostaglandins.

5.22.9 Neurotrophins and Sensitization of Tissues Other than Skin

The skin has attracted most of the attention in studies of the peripheral effects of neurotrophins. This is in keeping with the focus on this organ in investigations of somatosensory mechanisms. However, there is considerable evidence that NGF contributes to the sensitization of other tissues, specifically viscera, muscle, and joints, all of which are sites where inflammatory pain can occur.

5.22.9.1 Visceral Structures

Several investigators have observed enhanced levels of NGF in the bladder in models of interstitial cystitis, a normally painful condition (Oddiah, D. *et al.*, 1998; Toma, H. *et al.*, 2000; Bielefeldt, K. *et al.*, 2003). In human studies, the level of NGF determined in bladder biopsies was found to be higher in individuals whose condition is painful (Lowe, E. M. *et al.*, 1997). Using viral transfer methods, Lamb K. *et al.* (2004) demonstrated that enhancing NGF levels in rat bladder leads to overactivity measured cystometrographically. If NGF is neutralized using immunological methods, the bladder overactivity produced by external irritants is reduced (Lamb, K. *et al.*, 2003). NGF has also been demonstrated to be upregulated in other visceral organs such as the bowel in association with inflammatory conditions (di Mola, F. F. *et al.*, 2000) or in an animal model of pancreatitis (Toma, H. *et al.*, 2000).

5.22.9.2 Muscle Afferents

Recent studies have indicated that neurotrophins can influence the discharge of small-diameter muscle afferents. Hoheisel U. *et al.* (2005) evaluated the effect of intramuscular NGF on the discharge of small-diameter (Group IV) muscle afferents and found that only units with high mechanical threshold are facilitated. They reported that threshold is unchanged, but discharge frequency in response to adequate stimulation increases virtually immediately after NGF (0.8 μM) administration. Interestingly, they also observed that administration of BDNF (1 μM) causes a decline in discharge frequency, but only several minutes after administration.

The sensitization of high-threshold muscle afferents is consistent with the sensitization observed in response to intramuscular administration of NGF to the masseter muscle in humans (Svensson, P. *et al.*, 2003). Changes were observed 1 and 7 days after administration but not after 1 h and were described as consisting of both mechanical allodynia and hyperalgesia. Under pathological conditions, it seems likely that the cytokine TNFα is upregulated in muscle and that this leads to production of NGF (Schafers, M. *et al.*, 2003).

5.22.9.3 Joint Receptors

Synovial fluid from arthritic joints in humans expresses elevated levels of NGF (Falcini, F. *et al.*, 1996; Halliday, D. A. *et al.*, 1998), which has been attributed to elevated levels of cytokines such as TNFα and IL1-β (Manni, L. *et al.*, 2003), much as has been reported in skin (see Section 5.22.4.3). There have been no reports of enhanced sensitivity of joint afferents to mechanical stimulation in response to NGF although sensitization is known to occur in models of experimental arthritis (Schaible, H. G. and Schmidt, R. F., 1985). Joints treated with CFA have a more extensive innervation (Shinoda, M. *et al.*, 2003), possibly as a result of the enhanced levels of NGF known to promote terminal axonal sprouting in the skin (Diamond, J. *et al.*, 1992). An enhancement in peripheral axon terminals of trkA$^+$ nociceptive afferents might be expected to increase sensitivity to peripheral stimuli as a result of increased numbers of receptor molecules. Recently, Shelton D. L. *et al.* (2005) have demonstrated that administration of a monoclonal antibody against NGF (mAb 911, Rinat Neuroscience) can eliminate the pain associated with an experimental autoimmune arthritic condition in rats.

5.22.10 Nerve Growth Factor, Enhances Peptide Expression in the Dorsal Root Ganglion, and Central Sensitization

The ability of NGF to elicit rapid sensitization via posttranscriptional changes and to increase the expression of receptors and channels involved in setting the sensitivity and activity of nociceptors is indicative of its ability to enhance peripheral sensitization. However, NGF also elevates expression of peptides in the DRG ganglion and these are believed to enhance the central effects of glutamate released by nociceptors, i.e., to contribute to central sensitization (McMahon, S. B. *et al.*, 1993). Lindsay R. M. and Harmar A. J. (1989) were among the first to demonstrate that DRG cells maintained in culture exhibit enhanced levels of substance P and CGRP after exposure to NGF in the medium. These peptides are considered to be important mediators in central sensitization because of the very long-lasting depolarization that they produce in postsynaptic cells, leading to activation of the NMDA receptor (McMahon, S. B. *et al.*, 1993). Both NGF and GDNF enhance capsaicin-stimulated release of CGRP from cultured trigeminal ganglion neurons; however, the effect of GDNF is due entirely to the greater survival of these neurons in its presence (i.e., no change in response of individual neurons to capsaicin), whereas the effect of NGF is attributed in part to increased CGRP release per neuron, i.e., NGF sensitizes the response to capsaicin (Price, T. J. *et al.*, 2005).

The possibility for direct participation of neurotrophins in central sensitization was initially advanced by the finding *in vivo* that BDNF is also upregulated in the cell body of trkA receptor-expressing DRG cells several hours to days after exposure to NGF (Apfel, S. C. *et al.*, 1996; Michael, G. J. *et al.*, 1997). This suggested that BDNF would be released into the spinal cord, a prediction that has been borne out experimentally (Lever, I. J. *et al.*, 2001). The high-affinity receptor for BDNF, trkB, is found on neurons throughout the superficial dorsal horn (Bradbury, E. J. *et al.*, 1998; Garraway, S. M. *et al.*, 2003). A physiological role for BDNF has been established in models of inflammatory pain by demonstrating that sequestration of spinal BDNF using intrathecally delivered trkB-IgG diminishes the response to noxious heat (Kerr, B. J. *et al.*, 1999; Mannion, R. J. *et al.*, 1999; Pezet, S. *et al.*, 2002). In these experiments, it was also demonstrated that NGF has no central action, i.e., different neurotrophins act to promote peripheral and central sensitization (but see Section 5.22.11, indicating that BDNF and NT-4 can also elicit peripheral sensitization).

Direct physiological evidence for the action of BDNF in the superficial dorsal horn has come from experiments in spinal slices where it has been reported that BDNF facilitates the synaptic response of cells in lamina II to electrical stimulation of C-fibers both in neonates (Garraway, S. M. *et al.*, 2003) and in adults (Garraway, S. M. *et al.*, 2005). This facilitation of AMPA/kainate responses (measured in voltage clamp) is virtually immediate after superfusion of BDNF ($100\,\mathrm{ng\,ml^{-1}}$) and lasts for at least a few hours after washout of the BDNF. The effect of BDNF requires participation of NMDA receptors since it is blocked by APV. Additional pharmacological experiments have demonstrated a role for PKC in this process and also that administration of BDNF results in phosphorylation of the NMDA receptor in neurons in the superficial dorsal horn (Slack, S. E. *et al.*, 2004). It is important to note that BDNF itself does not elicit any detectable effect on lamina II neurons; it only acts to sensitize the response to stimulation of small-diameter sensory afferents. The neurotrophin effect is specific; superfusion of NT-3 does not sensitize this response (Garraway, S. M. *et al.*, 2003).

The requirement for functional NMDA receptors in order for BDNF to be effective in sensitizing the response of lamina II neurons to C-fiber input is consistent with the behavioral finding that pretreating rats for several days with systemic MK-801, an antagonist of NMDA receptors, selectively blocks the late phase of thermal and mechanical hyperalgesia elicited by NGF (Lewin, G. R. *et al.*, 1994). This late phase was attributed to central sensitization, whereas the acute phase, not affected by MK-801 treatment, was identified with peripheral sensitization. Thus, NGF exerts its effects by peripheral and central sensitization which together have been advanced as mechanisms to explain different components of hyperalgesia (McMahon, S. B. *et al.*, 1993).

5.22.11 Role of Brain-Derived Neurotrophic Factor, Neurotrophin-4, and Neurotrophin-3 in Peripheral Sensitization

There is increasing evidence that acute sensitization of nociceptors can be affected by neurotrophins other than NGF. Specifically, BDNF and NT-4 sensitize

nociceptive function acutely at the behavioral level (Shu, X. *et al.*, 1999), at the level of nociceptor discharge measured in isolated skin nerve preparations (Rueff, A. and Mendell, L. M., 1996; Shu, X. *et al.*, 1999), and at the level of capsaicin-activated TRPV1 currents measured in dissociated cells (Shu, X. and Mendell, L. M., 1999b). The proportion of small cells ($d \leq 30\,\mu m$) sensitized by NT-4 is similar to that sensitized by NGF. Therefore, it seems unlikely that trkA expression is required for cells to be sensitized by NT-4 since as a population, relatively few (10%) small $trkA^+$ sensory neurons also express trkB (Karchewski, L. A. *et al.*, 1999). Thus, activation of trkB alone can sensitize the response to capsaicin.

It is not known where trkB ligands would come from naturally in the periphery since there is no evidence at present that BDNF or NT-4 is upregulated in the skin immediately after inflammation. However, BDNF is upregulated in nerves undergoing Wallerian degeneration, opening the possibility that trkB ligands sensitize neurons after damage to neighboring nerve trunks. Another possibility is that BDNF, which is known to be released from the central terminals of nociceptors, would also be released from their peripheral terminals in the skin and that this would be the normal source of trkB ligands. Such a line of reasoning suggests that BDNF might act peripherally to reinforce the central sensitization it also elicits.

NT-3 does not elicit any acute sensitization of the response to noxious heat measured either electrophysiologically or behaviorally (Shu, X. *et al.*, 1999; Shu, X. and Mendell, L. M., 1999b) despite evidence that it can bind to trkA (Lindsay, R. M., 1996). However, 7-day exposure of $trkA^+/trkC^-$sensory neurons to NT-3 results in a substantial reduction in trkA receptor expression (Gratto, K. A. and Verge, V. M., 2003). Accompanying this loss of trkA is a decline in substance P levels. These studies suggest that NT-3 might have therapeutic value in diminishing painful states initiated by the activation of trkA.

5.22.12 Neurotrophins and Neuropathic Pain

Most considerations of neurotrophins and pain have centered on their role in inflammatory pain since they are naturally upregulated in the both periphery and DRG and play a prominent role in peripheral and central sensitization. However, there is also evidence that neurotrophins may contribute to the pain associated with nerve manipulations that are accepted as models for neuropathic pain. Thus, Zhou X. F. *et al.* (2000) have demonstrated that antibodies to NGF, BDNF, and NT-3 delivered to the DRG can reduce the pain associated with spinal nerve axotomy. Interestingly, antibodies to NGF elicit their effect in the early stages after injury, whereas BDNF and NT-3 antibodies exert their effects only later. In addition, Zhou X. F. *et al.* demonstrated that BDNF and NGF, but not NT-3, delivered to the DRG in intact preparations elicit mechanical allodynia. It is worth contrasting these findings with those of Kerr B. J. *et al.* (1999; see above) who showed that NGF delivered intrathecally elicits no nociceptive behavior. These differences presumably reflect the differences in the expression of trkA that is known to be present in the DRG, but not in the spinal cord. Theodosiou M. *et al.* (1999) carried out similar experiments with neurotrophin antibodies in rats subject to chronic partial axotomy of the sciatic nerve. They observed both mechanical and thermal hyperalgesia in these rats that could be relieved by antibodies to NGF or BDNF but not NT-3.

Fukuoka T. *et al.* (2001) have studied uninjured neurons in the L4 DRG in rats subjected to L5 spinal nerve ligation (Chung model). They observed an increase in BDNF mRNA levels in L4 associated with increased levels of expression as well as recruitment of additional neurons into the population of DRG neurons expressing BDNF mRNA. They also found that the enhanced sensitivity to noxious heat associated with this injury could be diminished temporarily by intrathecal application of an antibody to BDNF. Significantly, NGF appears to play a role in this enhancement of BDNF levels since NGF is increased in the DRG whose spinal nerve is ligated, and an antibody to NGF delivered to the injured DRG can prevent the upregulation of BDNF in the neighboring ganglion as well as the associated thermal hyperalgesia.

A recent study (Wilson-Gerwing, T. D. *et al.*, 2005) indicates that NT-3 can prevent the long-lasting increased expression of TRPV1 observed in the chronic constriction injury (CCI) model of neuropathic pain. They further demonstrated that NT-3 reduces expression of p38 MAPK shown to be a primary factor in the delayed elevation of TRPV1 expression in the skin (Ji, R. R. *et al.*, 2002). Treatment with NT-3-reduced thermal hyperalgesia, but not the mechanical hypersensitivity associated with CCI.

A different role for neurotrophins in neuropathic pain was reported by Bennett D. L. *et al.* (1996b) who

demonstrated that sprouting of peripherally axotomized Aβ-fibers into the superficial laminae of the spinal cord, considered to be a possible mechanism for neuropathic pain after such damage (Woolf, C. J. *et al.*, 1995), is reduced by application of NGF to the damaged nerve. They argued that this was not a direct effect of NGF on the sprouting of A-fibers since it would imply that sprouting is paradoxically reduced by administration of NGF. Also, large non-nociceptive Aβ-fibers do not express trkA, and so it is not clear how NGF would affect their sprouting. They proposed that NGF elicits sprouting of axotomized C-fibers that would reverse the A-fiber sprouting caused initially by the peripheral axotomy.

The pain associated with peripheral nerve damage has been shown to also have a microglial component. ATP released from damaged nociceptive afferents activates microglial P2 × 4 receptors; the activated microglia release BDNF which inhibits the KCC2 chloride transporter in lamin I cells (Coull, J. A., *et al.*, 2005). This shifts the chloride equilibrium potential in the depolarizing direction which changes the sign of inhibitory input toward excitation. This increases activity in nociceptive pathways contributing to pain. Thus, microglial BDNF as well as neuronal (DRG) BDNF can contribute to central sensitization. Interaction between these two sources of BDNF remains to be discovered.

Despite the lack of consistency, these experiments indicate several potential roles for neurotrophins in neuropathic pain. These are based on their ability to directly sensitize neuronal responses as well as their ability to elicit structural changes in the sensory nervous system.

5.22.13 Neurotrophins and the Clinic

The very strong sensitizing effect of neurotrophins on nociceptive pathways both peripherally and in the spinal cord has given them a very high profile in pain research. One of the earliest indications of a clinical effect emerged from Phase I clinical trials to determine the safety of NGF delivered systemically (Petty, B. G. *et al.*, 1994). NGF was administered subcutaneously or intramuscularly in human volunteers in amounts ranging from 0.03 to 1.0 $\mu g\,kg^{-1}$, dosages that are much lower than typically used in rats (1 $\mu g\,g^{-1}$). These subjects experienced myalgia in truncal and bulbar muscles as well as hyperalgesia at the site of injection. The latter could persist for up to 7 weeks. Similar human trials using single localized injections of NGF (1–3 μg per patient) in the arm resulted in localized allodynia and thermal hyperalgesia lasting several weeks (Dyck, P. J. *et al.*, 1997). These experiments in humans with verbal reports provide significant confirmation of the results from animal experiments. They also suggest that the use of NGF to increase cell survival or for other purposes will require measures to overcome the nociceptive side effects.

As discussed above, peripheral NGF levels are upregulated as a consequence of inflammation resulting in hyperalgesia. Furthermore, the hyperalgesia associated with inflammation can be largely eliminated by reducing NGF levels using either a sequestering antibody or a trkA immunoadhesin. This has prompted the development of NGF antibodies for eventual use in humans. Recently, Sevcik M. A. *et al.* (2005) reported that an antibody mAb 911 (Rinat Neuroscience Corporation) is effective in attenuating the pain in a mouse model of bone cancer whose sarcoma tumor cells are a source of high levels of NGF. As shown above (Section 5.22.9), bladder pain associated with models of cystitis is also associated with elevated expression of NGF, as is arthritic pain. Thus, we can expect that clinical trials using will be undertaken as soon as antibodies have been rendered safe for human use.

Several clinical conditions reported to be associated with alterations in NGF or trkA expression have been reviewed by Anand P. (2004). The trkA receptor is dysfunctional in individuals with congenital insensitivity to noxious stimulation, probably as a result of a mutation. Leprosy, a condition associated with hypoalgesia, is accompanied by reduced expression of NGF. Similar findings have been made in diabetic neuropathy. Conversely, the pain associated with injury to nerves has been correlated with enhanced expression of NGF in the associated nerve trunks. Together, these findings suggest that manipulation of neurotrophin levels may turn out to be a useful therapeutic approach to various conditions associated with disorders of nociception.

5.22.14 Discussion, Conclusions, and Open Questions

The past 15 years have seen an important expansion in our understanding of the role of neurotrophins as it has become generally accepted that they function throughout the life of the animal, not only during development. With regard to their effect on

nociception, it is clear that the survival of nociceptors is dependent on the integrity of the NGF/trkA system during the perinatal period. Beyond this period, the influence of NGF on nociceptors is very wide ranging (Petruska, J. C. and Mendell, L. M., 2004). NGF sensitizes nociceptors both acutely via post-transcriptional mechanisms (Figure 2) and chronically by enhancing the expression of numerous channels associated with nociceptors (Figure 4). These effects are exerted on nociceptors innervating many different tissues, including skin, muscle, joints, and viscera although at this time it is not yet known whether these neurons are regulated identically by NGF.

The discovery of the capsaicin receptor VR1/TRPV1 (Caterina, M. J. *et al.*, 1997), the revelation that this receptor mediated the response to noxious heat (Tominaga, M. *et al.*, 1998), and the finding that NGF could sensitize the response to capsaicin (Shu, X. and Mendell, L. M., 1999b) or to noxious heat (Galoyan, S. M. *et al.*, 2003) seemed to be entirely consistent with the behavioral evidence that NGF sensitizes the response to noxious heat. However, several experiments have raised difficulties with this simple picture. A substantial fraction of cell membrane patches from small-diameter sensory neurons were found to be sensitive to capsaicin (indicating TRPV1 expression) or noxious heat, but not both (Nagy, I. and Rang, H. P., 1999), suggesting that the receptor for capsaicin and for noxious heat are not the same. Furthermore, although two studies in dissociated cells from TRPV1$^{-/-}$ mice revealed the expected deficit in noxious heat sensitivity (Caterina, M. J. *et al.*, 2000; Davis, J. B. *et al.*, 2000), the same reports demonstrated that less reduced preparations (skin nerve or *in vivo* preparations) displayed considerable residual sensitivity to noxious heat. This raises questions concerning our model of how NGF acts to sensitize the response to noxious heat – specifically whether other noxious heat receptors exist (Woodbury, C. J. *et al.*, 2004) and whether these are affected by neurotrophins.

The finding that activation of the p75 receptor enhances membrane gain via by increasing TTX-insensitive Na current and decreasing the strength of K-rectification (see Section 5.22.7) expands possible mechanisms for sensitization by NGF. It also opens the possibility for sensitizing effects of other neurotrophins since p75, unlike trkA, trkB, and trkC, binds all the neurotrophins. The role of p75 in mediating the functional effects of NGF is still largely unknown.

Finally, the fact that NGF has so many different possible actions on nociceptive function in terms of the variety of cells that express trkA (Section 5.22.4.3) as well as the multiple effects that NGF can elicit in individual nociceptors (Sections 5.22.8 and 5.22.10) raises important questions about how all these mechanisms interact to cause sensitization. If the scheme outlined in Figure 2 is a complete representation of the peripheral mechanism of NGF action, one would expect that elimination of mast cells would reduce but not abolish NGF-induced sensitization. However, acute sensitization is abolished (Lewin, G. R. *et al.*, 1994), suggesting that NGF activation of the neutrophil pathway (Bennett, G. *et al.*, 1998b) or direct activation of nociceptor terminals is not sufficient to mediate the acute phase of NGF-induced hyperalgesia. Similarly, inhibiting neutrophil accumulation completely eliminates the hyperalgesic effect of NGF (Bennett, G. *et al.*, 1998b), indicating that the mast cell or direct effects are not sufficient either. Together, these findings suggest an interaction between these different mechanisms, and it will be important to dissect these interactions in order to more fully understand how NGF (and neurotrophins more generally) acts as a sensitizing agent for nociceptors. In view of increasing interest in manipulating NGF levels in a clinical setting, it will be necessary to understand its physiology at a more integrative level.

Acknowledgment

I thank Dr. Jeff Petruska for useful comments on an early draft of the manuscript and for help with figures. The author's research was supported by NIH (NS39420; NS16996) and the Christopher Reeve Paralysis Foundation Consortium on Spinal Injury.

Glossary

bouton Dilated portion of an axon possessing synaptic vesicles and establishing synapses with adjacent dendrites or other neuronal components. Synonyms – axonal varicosity or axon terminal.

presynaptic dendrite Dendrite possessing synaptic vesicles, and which is presynaptic to other neuronal processes, mainly dendrites. In the dorsal horn, presynaptic dendrites occur in islet cells.

substantia gelatinosa (of Rolando) Synonym of lamina II of Rexed. So named because of the translucent and gelatinous appearance when examined in fresh tissue.

superficial dorsal horn Region of the dorsal horn corresponding to laminae I and II of Rexed.

synaptic glomerulus (of the spinal cord) Complex synaptic arrangement in which a central axonal bouton, of primary sensory afferent origin, establishes synaptic contacts with several processes from dorsal horn neurons.

5.23.1 Introduction

The superficial laminae of the dorsal horn of the spinal cord, particularly the marginal layer (or lamina I of Rexed) and the substantia gelatinosa (or lamina II of Rexed), represent the area of the central nervous system (CNS) where the first modulation of pain-related information occurs. Although some progress has been made in recent years concerning our knowledge of the anatomical and neurochemical characteristics of the relevant cells and systems, our understanding of this area is far from complete. In particular, despite significant recent progress, our understanding of the synaptic circuitry and how neurotransmitters/neuromodulators in this region interact with their receptors is still incomplete, and even less is known about the changes that occur in acute and chronic pain (for recent review see Todd, A. J. and Ribeiro-da-Silva, A., 2005). This chapter presents an overview of what is known concerning the morphology and neurochemistry of the spinal dorsal horn, attempting to extract an emerging integrated view of the morphological and neurochemical organization in this area of the CNS from the available literature.

Because most of the work on the structure of the spinal cord has been carried out on the rat, we have based our description on this species, but when possible have made comparison to other species. We have focused on the superficial dorsal horn because of its relevance in the transmission and modulation of pain-related information.

5.23.2 Overall Organization of Dorsal Horn: Rexed Lamination

The first subdivision of the dorsal horn into horizontal laminae, based on the morphological properties of the cells in a Nissl-type staining, was performed in the cat dorsal horn (Rexed, B., 1952; 1954). It was later verified that this lamination could be adapted with minor modifications to almost any mammalian species. In particular, it has been adapted to the monkey (Ralston, H. J., III, 1979), human (Harmann, P. A. *et al.*, 1988), rat (Steiner, T. J. and Turner, L. M., 1972; Molander, C. *et al.*, 1984; 1989), and mouse (Ma, W. Y. *et al.*, 1995), besides nonmammalian species such as the pigeon (Leonard, R. B. and Cohen, D. H., 1975). Through a correlation of light and electron microscopy, it has been possible since the 1970s to establish criteria to identify the laminae at the ultrastructural level (for reviews see Light, A. R., 1992; Ribeiro-da-Silva, A., 2004).

Despite some recent criticism (Woodbury, C. J. *et al.*, 2000), the Rexed lamination remains the reference. Unfortunately, it is not always followed accurately, and many published micrographs show laminar limits that were based more on speculation rather than on objective evaluation using the proper approaches. This is true particularly for ultrastructural studies and also for those using radioactive ligand binding. This is unfortunate because, as we will discuss below, it is easy to set up the limits of the laminae with acceptable accuracy (see Figures 1 and 2 and below).

Besides neuroglia and vessels, the spinal dorsal horn contains several elements of neuronal origin: (a) the final arborization and termination of primary afferent fibers; (b) local circuit neurons, some excitatory and others inhibitory; (c) projection neurons to the brain; (d) propriospinal neurons, which interconnect different levels of the spinal cord; and (e) descending axons from several supraspinal sources.

Lamina I of the dorsal horn is also known as the marginal layer and lamina II as the substantia gelatinosa (of Rolando). These two laminae together represent what is frequently called the superficial dorsal horn and are of particular importance for the spinal processing of pain-related information and its forwarding to higher levels. This is true in particular for lamina I and the outer 2/3 of lamina II, as the inner 1/3 is mostly nonnociceptive. In contrast, laminae III–IV represent what is called the nucleus proprius, which was thought to represent a nonnociceptive region of the spinal cord. While this view is mostly valid, this region does contain neurons that are known to respond to noxious stimuli and project to the brain, which were initially thought to occur only in lamina V (De Koninck, Y. *et al.*, 1992; Ma, W. *et al.*, 1996).

Figure 1 shows the laminar organization of the rat spinal cord at the C4 level, as detected using a Nissl method on thick sections, and the correlation with laminae detected on semithin plastic sections. Although the criteria are quite different, there is a very good match between the laminae when identified by the Nissl approach and the semithin sections approach. When using a Nissl staining, lamina I can be recognized by a rather low cell density (Figure 1(a) and (1b)), with an occasional large neuron among mostly small cells. Lamina II is a layer with a higher density of cells than lamina I; these cells

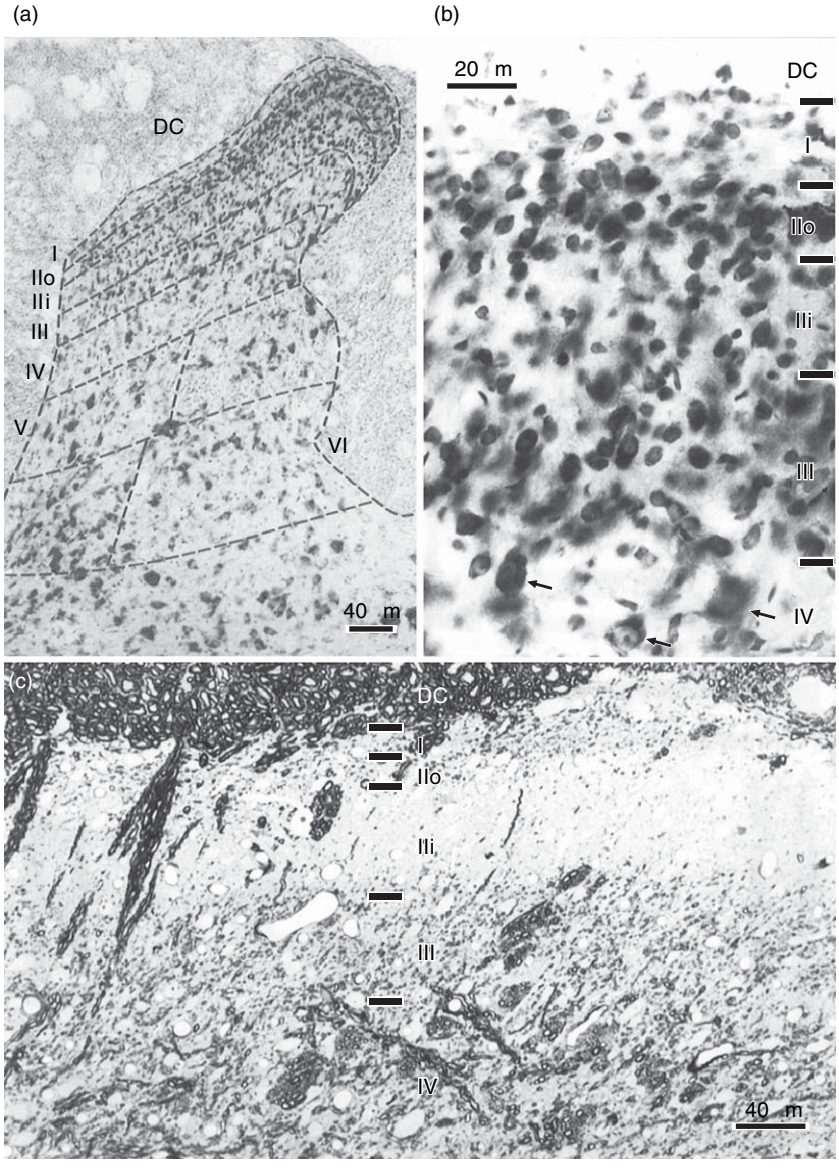

Figure 1 Rexed's laminae at the C4 level of the adult rat spinal cord. (a) and (b) represent micrographs from frozen cross sections, 50 μm in thickness, stained with toluidine blue as described by Rexed B. (1952). In (a), note the overall laminar organization of the dorsal horn. In (b), note that lamina I (I) has a low density of cells, whereas outer lamina II (LIIo) stands out because of the clustering of small neurons, which differentiate it from the inner part of lamina II (IIi). Both LIIo and inner lamina II (LIIi) have numerous small neurons, of rather uniform size. The presence of some slightly larger neurons separates lamina III from LIIi, whereas lamina IV can be easily distinguished from lamina III by the lower cell density and the presence of some large neurons. (c) represents a micrograph from an Epon-embedded semithin (2 μm thick) transverse section of the rat dorsal horn at the C4 level, stained with toluidine blue and Azur II, to illustrate that Rexed's laminae can be identified in these sections, which are used as reference for ultrastructural observations; notably, lamina IIi can be clearly delineated from lamina III by the absence of myelin (see text for details). DC, dorsal columns.

are rather small in size and occur in a considerably higher density in outer lamina II (LIIo) than in inner lamina II (LIIi). It should be noted that in many articles the subdivision of lamina II into outer and inner parts does not follow a cytoarchitectonic scheme as it should and some authors simply consider LIIo as the dorsal half of lamina II. Although in rat we have used lamina IIA to refer to LIIo and lamina IIB to refer to LIIi (see Ribeiro-da-Silva, A., 2004, for rationale), in the current chapter we will use

the nomenclature followed in most of the literature. The border between LIIi and lamina III is difficult to distinguish in Nissl-type preparations, as the main features are similar except for the presence of some larger cells in lamina III. Lamina IV, in contrast, is easy to distinguish from lamina III because of the lower cell density and the presence of some rather large neurons (Figure 1(b)).

The superficial laminae can also be recognized in Epon-embedded 1–2-μm-thick semithin sections stained with toluidine blue, as this approach has been validated by integrated light and electron microscopic studies (Ribeiro-da-Silva, A. and Coimbra, A., 1982). In these preparations, lamina I can be distinguished from LIIo by the presence of a higher density of small myelinated fibers, whereas LIIi is virtually devoid of myelin (Figure 1(c)). In contrast, lamina III is easily distinguished from IIi by the appearance of numerous thinly myelinated fibers (Figure 1(c)).

At mid-lumbar levels, which represent the region innervating the hind limbs and which has been studied extensively, the thickness of the superficial laminae is greater in the medial 2/3 than in the lateral third. Overall the thickness of LI and LIIo is twice the value of mid-cervical levels. Figure 2 illustrates the laminar subdivisions at the level of the L5 segment of the young rat spinal cord.

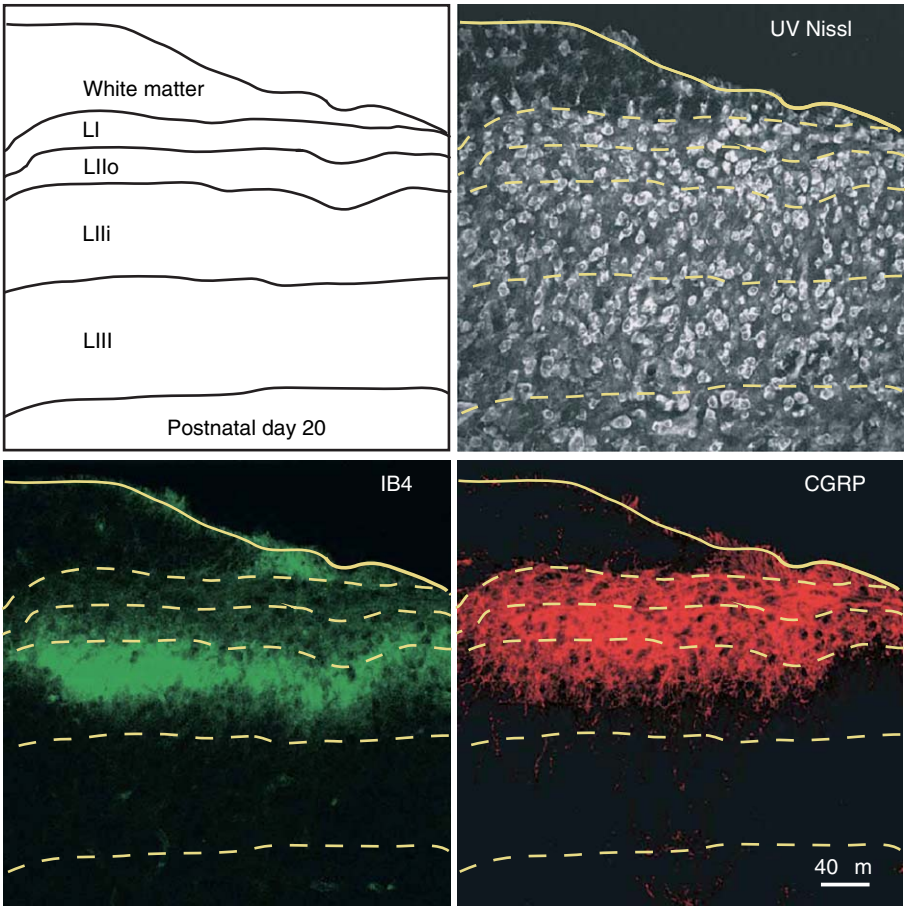

Figure 2 Rexed's laminae at the L5 level of the spinal cord of a young rat (20-day old). Micrographs represent confocal images that result from the fusion of several optical sections obtained using a multitrack approach on a 50-μm-thick transverse section. Section was immunostained for calcitonin gene-related peptide (CGRP) and incubated for IB4 binding and a Nissl-type labeling using an ultraviolet fluorescent marker. The Nissl-type labeling was used to identify the Rexed's laminae and to create an overlay, which was applied to the other images, and is shown isolated in the upper left picture. This figure clearly illustrates that CGRP immunostaining occurs in lamina I (LI), outer lamina II (LIIo), and part of inner lamina II (LIIi), whereas IB4 labeling is most intense in the dorsal part of LIIi. Because the thickness of each lamina is rather constant at the same level of the spinal cord, overlays created like this are useful to identify the laminae even in material not stained with a Nissl method.

5.23.3 Primary Afferent Fibers

5.23.3.1 Types of Afferents, Neurochemistry, and Termination in Spinal Cord

The great majority of afferents that transmit pain-related information (nociception) are of small diameter and have unmyelinated (C) or thinly myelinated (Aδ) axons. Most such small-diameter fibers convey pain-related information and, therefore, are often named nociceptors. These small-diameter fibers represent the central processes of pseudounipolar neurons of small or medium size located in the dorsal root ganglia (DRG) and terminate in the superficial laminae of the dorsal horn of the spinal cord (for reviews see Grant, G. and Robertson, B., 2004; Ribeiro-da-Silva, A., 2004). The smaller-diameter (unmyelinated) nociceptive afferents can be divided into two major subpopulations, the peptidergic and the nonpeptidergic. The peptidergic expresses substance P (SP) and calcitonin gene-related peptide (CGRP), and the nonpeptidergic possesses fluoride-resistant acid phosphatase (FRAP) activity, binds the lectin GSA-IB4, and expresses purinergic $P2X_3$ receptors (Hunt, S. P. and Rossi, J., 1985; Alvarez, F. J. and Fyffe, R. E., 2000; Hunt, S. P. and Mantyh, P. W., 2001). These two populations differ in neurotrophic support in the adult. In fact, during development, both populations require nerve growth factor (NGF) for survival, but shortly after birth only the peptidergic continues to respond to NGF, whereas the nonpeptidergic population starts to respond instead to glial cell line-derived neurotrophic factor (GDNF) (Bennett, D. L. H. *et al.*, 1998). Accordingly, the peptidergic population expresses the NGF high-affinity receptor, trkA, whereas the nonpeptidergic expresses GDNF receptors. It has also been shown that the latter population expresses the purinergic receptor $P2X_3$ (Bradbury, E. J. *et al.*, 1998; Snider,W. D. and McMahon, S. B., 1998). Although the distinction between two populations of primary sensory fibers, peptidergic and nonpeptidergic, seems attractive, it is not fully accurate as a small proportion of peptidergic sensory fibers (those that colocalize CGRP and somatostatin (SOM)) do not respond to NGF in the adult and bind the lectin GSA-IB4 (Alvarez, F. J. and Fyffe, R. E., 2000; Priestley, J. V. *et al.*, 2002). It should be noted that, in all of the above putative nociceptive fibers, the classical synaptic transmitter is very likely glutamate (Battaglia, G. and Rustioni, A., 1988; De Biasi, S. and Rustioni, A., 1988; Merighi, A. *et al.*, 1991). In the spinal cord, sensory fibers that express SP and CGRP terminate mostly in laminae I, outer II, and lamina V; those that colocalize CGRP and SOM terminate in laminae I and II, and those that contain FRAP, bind the lectin GSA-IB4 or express the purinergic $P2X_3$ receptor, terminate mostly in the middle third of lamina II (see Figure 2; for reviews see Bradbury, E. J. *et al.*, 1998; Ribeiro-da-Silva, A., 2004). Not all the nociceptive afferents that express SP are C fibers; some are thinly myelinated (Aδ) afferents. There is a significant population of nociceptive fibers that are Aδ and were shown to represent high-threshold mechanoreceptors (HTM) after being characterized electrophysiologically and filled intracellularly with horseradish peroxidase in cat and monkey; they were shown to terminate in laminae I and V (Light, A. R. and Perl, E. R., 1979). The morphological and neurochemical identification of these Aδ HTM fibers is difficult because they do not contain peptides, do not bind IB4, and do not express $P2X_3$ receptors. However, there is evidence from an *in situ* hybridization study that the 5-HT3 may be highly expressed by Aδ HTM fibers (Zeitz, K. P. *et al.*, 2002). Although the prevailing view is that Aβ fibers are nonnociceptive, it has been suggested that some of the myelinated nociceptors conduct in the Aβ range. In rat, these Aβ nociceptors might represent up to 20% of all Aβ somatic afferents according to some reports (for review see Djouhri, L and Lawson, S. N., 2004).

Although a small number of C fibers are nonnociceptive and convey either innocuous mechanical or thermal information, most nonnociceptive mechanosensitive afferents are either thinly myelinated (Aδ) or thick afferents (Aβ) (Alvarez, F. J. and Fyffe, R. E., 2000). Most innocuous Aδ afferents innervate down hairs (D hair afferents) and terminate in the deeper part of lamina II and in lamina III, a distribution that contrasts with the preferential termination of nociceptive Aδ afferents in laminae I and V (Light, A. R. and Perl, E. R., 1979). Like the nociceptive fibers, the nonnociceptive afferents are glutamatergic (Battaglia, G. and Rustioni, A., 1988; De Biasi, S. and Rustioni, A., 1988; Merighi, A. et al., 1991). Curiously, the T-type calcium channel Cav3.2 seems to be expressed exclusively by D hair afferents, as detected by in situ hybridization at the level of the DRG (Shin, J. B. et al., 2003).

It should be noted that other neuropeptides have been localized in the fibers that contain SP and CGRP: neurokinin A (Dalsgaard, C. J. *et al.*, 1985), galanin (Ju, G. *et al.*, 1987; Zhang, X. *et al.*, 1993), and

Table 1 Overview of the classical transmitter and peptidergic innervation of the spinal dorsal horn of the rat, as described in text

Origin of neurotransmitter/neuropeptide			
>Primary afferents	***Local circuit neurons***	***Neurons projecting to brain***	***Descending fibers***
Glu + SP[a] + CGRP + End-2 + (Gal[b]) + (CCK[c]) + (VIP[c])	Glu + SP + ENK	Glu + SP + ENK	5-HT + SP + TRH
Glu + SOM + CGRP	Glu + NKB	Glu + dynorphins (?)	5-HT + ENK
Glu + dynorphin B (at sacral levels) + ?	Glu + SOM	Glu + Gal + CCK	GABA
Glu + ?	Endomorphin-1 + ?		GABA + Gly
Glu + (NPY[c])	GABA + ENK		Noradrenaline
	GABA + Ach		
	GABA + NPY		
	Glu + Gal + CCK (?)		
	Glu + dynorphins (?)		
	Glu + neurotensin		

[a]All neurons that express SP colocalize NKA in rat. Neurochemical in parenthesis are not expressed or expressed in a reduced number of afferents in the absence of lesion.
[b]Galanin is strongly upregulated after nerve lesion.
[c]These peptides are expressed only in a significant number of primary afferents following peripheral nerve lesion.
This table does not intend to be a complete list. It is restricted to the peptides mentioned in the text.
Abbreviations: Ach, acetylcholine; CCK, cholecystokinin; CGRP, calcitonin gene-related peptide; End-2, endomorphin 2; ENK, enkephalin; Gal, galanin; Glu, glutamate; NKA, neurokinin A; NKB, neurokinin B; NPY, neuropeptide Y; SP, substance P; SOM, somatostatin; TRH, thyrotropin-releasing hormone; VIP, vasocative intestinal peptide.

the opioid peptide endomorphin-2 (Martin-Schild, S. *et al*., 1997; Martin-Schild, S. *et al*., 1998). Dynorphin B has been detected in some primary sensory fibers from visceral afferents from pelvic viscera at sacral levels in the cat (Basbaum, A. I. *et al*., 1986). Some neuropeptides are not expressed in any significant amount in primary sensory fibers in naïve rats but are upregulated following peripheral axotomy: vasoactive intestinal peptide (VIP) and cholecystokinin (CCK) appear on small, peptidergic afferents, whereas neuropeptide Y (NPY) appears in large-diameter afferents (for review see Hökfelt, T. *et al*., 1994). Table 1 gives an overview of classical transmitters and peptides in the dorsal horn, including those in the terminals of primary sensory fibers.

5.23.3.2 Synaptic Arrangements of Primary Afferents

In the dorsal horn, primary afferent boutons establish mostly simple axodendritic, and to a lesser extent, axosomatic synapses. However, a significant proportion of primary afferent endings participate in complex arrangements named synaptic glomeruli, where they form the central terminal (Coimbra, A. *et al*., 1974; Ribeiro-da-Silva, A. and Coimbra, A., 1982). Glomeruli represent multiplier systems, i.e., devices that transmit sensory information to several dorsal horn neurons. They also constitute important modulatory devices as the primary afferent terminals are often postsynaptic to other neuronal profiles. Since the central terminals of glomeruli are all of primary afferent origin, as has been shown by their complete disappearance following multiple dorsal rhizotomies (Coimbra, A. *et al*., 1984), they provide a very useful means of identifying these afferents with electron microscopy, without the need for transported or immunocytochemical markers. The detailed features of synaptic glomeruli in the rat have been reviewed in a recent publication (Ribeiro-da-Silva, A., 2004). To be classified as a synaptic glomerulus, a synaptic arrangement must meet simultaneously all of following criteria when viewed in a single ultrathin section: (a) it should possess a central terminal (C) with round synaptic vesicles; (b) this C terminal has to be surrounded by at least four neuronal profiles, representing either dendritic profiles or axonal bouton profiles; (c) there have to be at least two visible synaptic contacts between the central bouton profiles and the peripheral profiles. Two main types of synaptic glomeruli have been identified in rat by Ribeiro-da-Silva A. and Coimbra A. (1982), and are named type I and type II. Glomeruli of type I have a central bouton of scalloped contour, with an electrondense matrix, with rather densely packed synaptic vesicles and a low density of mitochondria, whereas type II

glomeruli are larger and possess a central terminal, which has a rounder contour, a lighter cytoplasmatic matrix, synaptic vesicles, which are more uniform in size and less densely packed, and a higher density of mitochondria (Ribeiro-da-Silva, A. and Coimbra, A., 1982). This classification is applicable to the mouse and, with some modifications, to the cat and the monkey (unpublished observations). A comparable classification was established for the monkey dorsal horn (Knyihár-Csillik, E. *et al.*, 1982b), in which three glomerular types were described, based on the properties of their central terminals. Of the three types described in the monkey by Knyihár-Csillik E. *et al.* (1982b), the dense sinusoid axon (DSA) type corresponds to the type I of Ribeiro-da-Silva A. and Coimbra A. (1982) and the regular synaptic vesicles (RSV) type corresponds to type II. Although the large dense-core vesicle (LDCV) type of Knyihár-Csillik E. *et al.* (1982b) has apparently no equivalent in the classification of Ribeiro-da-Silva A. and Coimbra A. (1982), this type has been considered in rat as a subtype of type I (subtype Ib), as in this species most of their central terminals share the dark axoplasm, the sinuous contour, and small size with type I central boutons, although they display numerous dense-core vesicles (Ribeiro-da-Silva, A. *et al.*, 1989; Ribeiro-da-Silva, A., 2004). However, the incorporation of these glomeruli with dense-core vesicles in type I is not legitimate in cat and monkey, as in these species they have larger central boutons, with more mitochondria and a lighter matrix than in rat. Therefore, for the sake of simplicity, we propose that in cat and primates, glomeruli can be classified into type I, type II, and peptide-type (because all the central boutons of this later type express neuropeptides – see below). In rat both type Ia and type II glomeruli have complex synaptic arrangements in which the central bouton is postsynaptic to presynaptic dendrites and axonal boutons and presynaptic to both normal dendrites and presynaptic dendrites (see Figure 3 for details). One main feature of peptide-type synaptic glomeruli (type Ib in rat) is that their central terminal is seldom postsynaptic to presynaptic dendrites and peripheral axons.

Of the nociceptive afferents, the nonpeptidergic, IB4-binding afferents terminate mostly as central boutons of synaptic glomeruli of type I (or more precisely in rat of subtype Ia), whereas the peptidergic endings are glomerular in only a small proportion, particularly in rat (Ribeiro-da-Silva, A. *et al.*, 1989); when they are glomerular, the central boutons (subtype Ib) contain dense-core vesicles and peptide immunoreactivity (CGRP, together with either SP or SOM; Ribeiro-da-Silva, A., 1995). Concerning nonnociceptive boutons, many terminate as central boutons of type II synaptic glomeruli (e.g., the D-hair afferents), but many are nonglomerular, including the ones corresponding to the termination of G-hair afferents, based on the data obtained in the cat (for review see Maxwell, D. J. and Réthelyi, M., 1987). Figure 4 shows a diagrammatic representation of the different types and subtypes of synaptic glomeruli in rat. There are considerable species differences in the type of synaptic arrangements of primary sensory fibers. For instance, lamina I and LIIo are virtually devoid of synaptic glomeruli in rat (Ribeiro-da-Silva, A. and Coimbra, A., 1982), but not in cat or monkey; in this latter species, there are, in laminae I and IIo, numerous type II glomeruli corresponding to the termination of the HTM myelinated nociceptors (Réthelyi, M. *et al.*, 1982), which are nonglomerular in rat, as well as a considerable number of peptide-type glomeruli (Knyihár-Csillik, E. *et al.*, 1982b), which are sparse in rat.

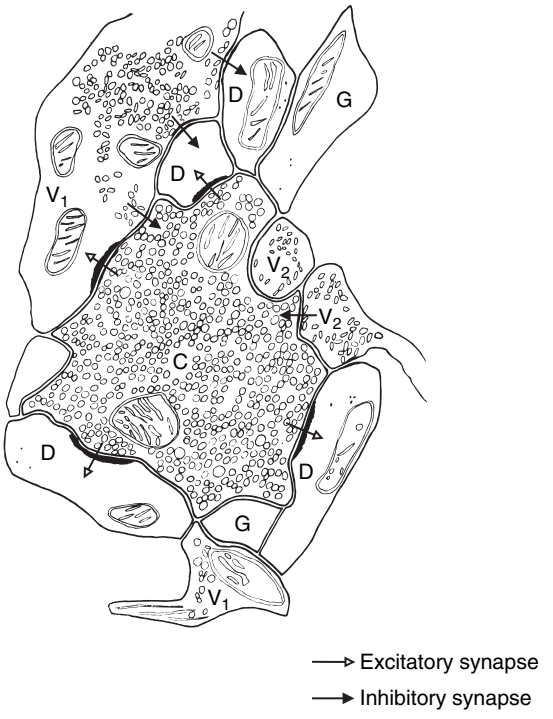

Figure 3 Diagram of a synaptic glomerulus of type Ia, with representation of the complex synaptic arrangements of the triadic type. The drawing was inspired by an electron micrograph of a type Ia glomerulus and shows the morphological features and the synaptic circuits involving the central bouton, of primary sensory origin, and the peripheral profiles. C, Central bouton; D, regular dendrite; V_1, presynaptic dendrite; V_2, peripheral axonal bouton; G, glial profile.

	Type Ia	Type Ib	Type IIa	Type IIb
I				
IIo	++	+		
IIIdorsal	++++++	++	+	
IIIventral	+++		+++++	++
III			++++	++++
Afferent innervation	Nonpeptidergic C fibers (IB4 and P2X3)	Peptidergic (CGRP + SP CGRP + SOM)	Aδ fibers D-Hair (?)	Aβ fibers (?)

Figure 4 Types of synaptic glomeruli and their laminar incidence in laminae I–III of the rat dorsal horn. The drawings on top were inspired by actual electron micrographs of representative samples of each glomerular type. Note that in rat, lamina I (I) is virtually devoid of glomeruli and that outer lamina II (LIIo) has only a low number of them. This is a considerable difference when comparing to the cat and primate, which have glomeruli in significant numbers in lamina I and outer II. In contrast, the other laminae have abundant synaptic glomeruli. Most type Ia glomeruli are condensed in a rather narrow band (~20 μm thick at cervical levels), which represents the dorsal part of inner lamina II (III_{dorsal}). Most of the inner lamina II ($III_{ventral}$) has a predominance of type IIa glomeruli, whereas lamina III is normally devoid of type I glomeruli and has similar numbers of both subtypes of type II glomeruli. The data concerning laminar incidence of glomeruli are semiquantitative and are based on the data collected from other publications (Ribeiro-da-Silva, A. and Coimbra, A., 1982; Ribeiro-da-Silva, A. *et al.*, 1989). The information on the types of afferent fibers, which terminate as central boutons of each type of glomerulus, is either based on evidence obtained in rat (for type I glomeruli) or extrapolated from the data obtained in cat and primate. See text for details on glomerular classification.

It is important to stress that of the populations of nociceptive primary sensory fibers, the peptidergic is not postsynaptic to GABAergic neurons in the species studied (Alvarez, F. J. *et al.*, 1993; Ribeiro-da-Silva, A., 2004). In contrast, in rat, the IB4-binding population (which terminates as central boutons of glomeruli of type Ia) is postsynaptic to GABAergic neurons (Todd, A. J. and Lochhead, V., 1990; Ribeiro-da-Silva, A., 2004). In cat and primates, the HTM myelinated nociceptors that terminate in synaptic glomeruli are also postsynaptic to dorsal horn neurons at synapses, which have the morphological properties of inhibitory junctions or in which the profiles have been shown to express GABA (Réthelyi, M. *et al.*, 1982; Alvarez, F. J. *et al.*, 1992). There seem to be species differences though, as a primate study has shown that the terminals that have the morphology of the IB4 nonpeptidergic population of the rat did not show them to be involved in axo- or dendroaxonic synapses (Knyihár-Csillik, E. *et al.*, 1982a). Similarly, in rat the HTM myelinated nociceptors are not glomerular and not postsynaptic to other structures. The above indicates different presynaptic control of the different type of nociceptive inputs, as well as likely species differences in such presynaptic control.

5.23.3.3 Receptors on Primary Sensory Fibers

Receptors expressed on primary afferent terminals in the spinal dorsal horn include neurotransmitter/modulator receptors and neurotrophic factor receptors. It is important to point out that most of the past studies of the neurotransmitter/modulator receptors on primary afferents have been performed in the dorsal root ganglia. Information on localization of receptors on the terminals of primary sensory fibers in the spinal cord is recent and still rather limited as it

required the development of specific antibodies against the neurotransmitter/modulator receptors.

Concerning glutamate receptors, α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptors have a widespread distribution in DRG neurons (Tachibana, M. *et al.*, 1994; Lu, C. R. *et al.*, 2002). It has been shown at the light and ultrastructural levels that *N*-methyl-D-aspartic acid (NMDA) receptors occur in sensory fibers in the dorsal horn (Liu, H. *et al.*, 1994b). A presynaptic localization of sensory fibers in the dorsal horn has also been shown for kainate (Hwang, S. J. *et al.*, 2001) and metabotropic glutamate receptors (Ohishi, H. *et al.*, 1995). It is important to note that while ionotropic glutamate receptors are typically viewed as excitatory, their activation on primary afferent terminals leads to inhibition of transmitter release, likely via primary afferent terminal depolarization (PAD) akin to the action of presynaptic $GABA_A$ receptors (Kerchner, G. A. *et al.*, 2001; Lee, C. J. *et al.*, 2002; Bardoni, R. *et al.*, 2004). This contrasts with the apparent excitatory role that glutamate receptors appear to play at the peripheral endings of primary afferents (Cairns, B. E. *et al.*, 1998; Svensson, P. *et al.*, 2003). To further complicate the matter, PAD appears to have an opposite effect on spontaneous transmitter release (facilitation) versus evoked release (inhibition) (for review see Engelman, H. S. and MacDermott, A. B., 2004). Subunits of the $GABA_A$ receptor have also been identified by *in situ* hybridization in DRG neurons (Persohn, E. *et al.*, 1991), consistent with the functional evidence of a role for these receptors in presynaptic inhibition of primary afferents (for review see Rudomin, P. and Schmidt R. F., 1999). Intriguingly, however, to date it has not yet been possible to immunocytochemically label $GABA_A$ receptor subunits at axoaxonic synapses in the dorsal horn, although they have been labeled in dorsal horn neurons (Alvarez, F. J. *et al.*, 1996; Todd, A. J. *et al.*, 1996). There also appears to be a difference in the strength of $GABA_A$ receptor-mediated responses between subtypes of small-diameter afferents (Labrakakis, C. *et al.*, 2003). Subunits of the metabotropic $GABA_B$ receptor have been identified in DRG neurons and, in the dorsal horn, in dendrites and central boutons of glomeruli (Poorkhalkali, N. *et al.*, 2000; Ribeiro-da-Silva and Shigemoto, unpublished observations).

Concerning opioid receptors, it is well established that they occur in primary sensory fibers. The evidence originates from studies using radioactive ligand binding, which show that both μ- and δ-opioid receptors in the dorsal horn are reduced following dorsal rhizotomy (Fields, H. L. *et al.*, 1980), and from *in situ* hybridization studies, which have shown that mRNA for each of the main opioid receptors (μ, δ, and κ) occurs in DRG neurons (Minami, M. *et al.*, 1995).

There is both immunocytochemical and *in situ* hybridization evidence that the SP receptor, the neurokinin 1 receptor (NK-1r), occurs in DRG cells and on sensory fibers in the periphery (Ruocco, I. *et al.*, 1997; Li, H. S. and Zhao, Z. Q., 1998). Surprisingly, the NK-1r cannot be detected by immunocytochemistry on terminals of primary sensory fibers in the spinal dorsal horn, an observation that suggests that the NK-1r synthesized in DRG neurons is targeted preferentially toward the periphery. In contrast, the NK-1r occurs in well-defined populations of dorsal horn neurons, as described below.

The capsaicin receptor, TRPV1, previously named VR1 (Caterina, M. J., 2003), occurs in small diameter primary sensory afferents. Unfortunately, there is conflicting evidence in the literature regarding which afferent populations express the receptor. The *in situ* hybridization data of Michael G. J. and Priestley J. V. (1999) concluded that it is expressed by the majority of small- and medium-sized dorsal root ganglion neurons, which label with the lectin IB4 or are CGRP-immunoreactive (IR). In contrast, using immunocytochemistry Guo A. *et al.* (1999) concluded that TRPV1 occurred mainly in the nonpeptidergic, IB4-binding afferents, and to a minor extent in the peptidergic as well. An important observation is that there was a phenotypic switch in the postnatal period leading to the progressive expression of TRPV1 in DRG neurons that bind the lectin IB4, whereas the population that colocalized peptides did not change (Guo, A. *et al.*, 2001). Furthermore, a very significant species difference does occur because in mouse TRPV1 is not expressed by the IB4-binding population of afferents but rather by the peptidergic population (Zwick, M. *et al.*, 2002), suggesting that the phenotypic switch, which occurs postnatally in the rat, does not take place in the mouse. This is a particularly important point as it suggests that the results obtained with TRPV1 knockout mice are not transposable to the rat.

The purinergic receptor $P2X_3$ has been detected in the nonpeptidergic population of nociceptive afferents (Bradbury, E. J. *et al.*, 1998) and, in agreement with this, in the central boutons of glomeruli of type I (Llewellyn-Smith, I. J. and Burnstock, G., 1998). Because of the variability with the conditions of incubation in a number of afferents that are labeled by IB4 binding (see Alvarez, F. J. and Fyffe, R. E.,

2000, for a discussion), $P2X_3$ immunostaining may represent a better way of identifying the nonpeptidergic subpopulation of C fibers.

Concerning cholinergic receptors on primary sensory fibers, both nicotinic and muscarinic receptors have been identified (Flores, C. M. *et al.*, 1996; Haberberger, R. *et al.*, 1999). Concerning adrenergic receptors, both $\alpha 1$ and $\alpha 2$ receptors have also been localized in the DRG neurons (Kinnman, E. *et al.*, 1997; Birder, L. A. and Perl, E. R., 1999; Xie, J. *et al.*, 2001), and there is also some evidence that they occur in nociceptive primary afferents in the spinal cord (Stone, L. S. *et al.*, 1998). Because α-adrenergic receptors in the DRG are upregulated after peripheral nerve lesion, these receptors may be implicated in the sensitization of primary afferents in sympathetically maintained pain.

There is abundant literature on the expression of trophic factor receptors by primary sensory fibers (for review see Priestley, J. V. *et al.*, 2002). All three high-affinity neurotrophin receptors, trkA, trkB. and trkC, have been detected in DRG neurons. Of these, trkB and trkC occur in large-diameter neurons, corresponding to low-threshold mechanoreceptors, whereas trkA is found in nociceptive neurons that express the neuropeptides CGRP and SP. The low-affinity neurotrophin receptor, p75, has been identified in the populations of DRG neurons that express one of the high-affinity neurotrophin receptors. The nonpeptidergic, IB4-binding population, including its subpopulation that colocalizes CGRP and SOM, expresses in the adult components of the GDNF receptor family, but not in neurotrophin receptors (Alvarez, F. J. and Fyffe, R. E., 2000).

5.23.3.4 Expression of Voltage-Gated Sodium Channels by Sensory Fibers

In recent years, there has been a developing interest on voltage-gated sodium channels expressed by primary sensory fibers, as changes in some have been linked to pain states (for review see Wood, J. N. *et al.*, 2004). Channels with α subunits coded by the $Na_v1.8$ and $Na_v1.9$ genes are sensory neuron-specific and commonly referred to as tetrodotoxin (TTX)-resistant because higher doses of TTX are required to block them (Amaya, F. *et al.*, 2000). Although the two channels are mostly colocalized in the same DRG neurons in the rat (Amaya, F. *et al.*, 2000), the $Na_v1.8$ channel also occurs in some larger-diameter afferents, as was demonstrated in a study in which the physiological properties of the neurons expressing it was studied in the DRG (Djouhri, L. *et al.*, 2003) and by immunocytochemistry, which shows that $Na_v1.9$ channel immunoreactivity is restricted to laminae I–II whereas some $Na_v1.8$ signal was detected in the deeper laminae as well (Amaya, F. *et al.*, 2000). Regarding small-diameter afferents that express these channels, both channels seem to be expressed equally by peptidergic and nonpeptidergic (IB4-positive) afferents, although such expression was present only in about 50% of trkA-positive and 50% IB4-positive neurons (Amaya, F. *et al.*, 2000). However, a recent study in the mouse indicated that, in this species, the $Na_v1.8$ channel is expressed by 80% of the IB4-binding population of sensory fibers and only by 20% of the CGRP-IR (Braz, J. M. *et al.*, 2005), which would suggest that there are significant species differences in the relative expression of these channels. Of the TTX-sensitive channels, the $Na_v1.7$ channel is also expressed selectively in nociceptive, small-diameter afferents, although it also occurs in sympathetic neurons, and seems to play a major role in acute and inflammatory pain (Nassar, M. A. *et al.*, 2004). Interestingly, mutations that cause loss of function of $Na_v1.7$ were recently found in three consanguineous families from northern Pakistan characterized by complete inability to sense pain (Cox, J. J. *et al.*, 2006).

5.23.4 Dorsal Horn Neurons

The great majority of neurons in each lamina of the dorsal horn are local circuit neurons (interneurons), with axons that remain in the spinal cord. It should be noted that laminae I and V also possess predominantly interneurons, despite the fact that they are normally regarded as the origin of major ascending nociceptive pathways to the brain. These interneurons participate in synaptic circuits, which unfortunately are still very incompletely known. To complicate matters, there is evidence of considerable interspecies differences. These differences affect the distribution and synaptic connections of primary sensory fibers as well as the neurotransmitter/neuropeptide colocalization and the ascending pathways. It certainly does not help that most immunocytochemical studies on physiologically characterized, intracellularly filled neurons were performed in the cat, whereas most of those based on a combination of tract tracing and immunocytochemistry are from the rat and the monkey, and studies on transgenic animals were performed in the mouse.

The primary sensory fibers terminate in the dorsal horn in contact with both interneurons and projection neurons. Unfortunately, our knowledge concerning the details of the termination of specific fiber populations on identified dorsal horn neurons is extremely limited, because a systematic study combining intracellular recordings and labeling of sensory fibers with labeling of dorsal horn neurons has never been done for the nociceptive afferents. This lack of information from intracellular techniques is not a major issue for the SP afferents that innervate neurons that express the NK-1r because the available antibodies label the NK-1r-IR dorsal horn neurons extremely well, in a Golgi-like manner, which allows their morphological characterization. Because of this, we have rather detailed information on NK-1r-positive neurons innervated directly by SP, including their supraspinal projection sites (for recent review see Todd, A. J. and Ribeiro-da-Silva, A., 2005). Unfortunately, the same is not true for the termination of the nonpeptidergic population of nociceptive fibers in the dorsal horn, despite the fact that their endings can be identified directly on electron micrographs (EM) without the need of any label, because of their unique morphology as type I glomeruli central boutons (Ribeiro-da-Silva, A., 2004). In fact, it is still unknown if the central boutons of type I glomeruli synapse directly on the projection neurons or if there is an interposed interneuron. Recent evidence demonstrates a pathway for nonpeptidergic afferents connecting to lamina I neurons via lamina IIi interneurons (Lu, Y. and Perl, E. R., 2005) (given that the great majority of the C fibers that innervate lamina IIi are from the nonpeptidergic subpopulation; see also below). A challenging alternative has been proposed recently in a study using a transgenic mouse endogenously expressing a tracer transported transsynaptically in the nonpeptidergic afferents that express the $Na_V1.8$ channel. This study has shown that these afferents are connected to lamina II interneurons that link primarily to lamina V projection neurons that, in turn, target fourth-order neurons in the amygdala, hypothalamus, bed nucleus of the stria terminalis, and globus pallidus (Braz, J. M. *et al.*, 2005). The $Na_V1.8$ subclass of nonpeptidergic, IB4-binding afferents demonstrated in mice would thus likely be distinct from the putative subclass that would connect to lamina I via lamina IIi based on the studies by Lu Y. and Perl E. R. (2003; 2005) in the rat. It remains to be determined whether this is a species difference and how these pathways transpose to other species.

5.23.4.1 Lamina I Neurons

5.23.4.1.1 Morphological classification of lamina I neurons

Four morphological types of neurons have been described in the rat by Lima D. and Coimbra A. (1983; 1986): fusiform, flattened, multipolar, and pyramidal (Figure 5). Most of these neurons have their perikarya and dendritic arborization extending predominantly in the rostrocaudal axis, but with some processes extending along the mediolateral axis. For most cells, the dendrites remain within the limits of lamina I. However, some specific cell subtypes have been described with dendrites extending into laminae II and III (Figure 6); these represent a small proportion of the total number of cells that may represent local circuit neurons (Yu, X. H. *et al.*, 2005), although the possibility remains that they project to another supraspinal site different from the thalamus and the parabrachial nucleus (Lima, D. and Coimbra, A., 1990; Almarestani, L. *et al.*, 2007). Antidromic recording and retrograde labeling with horseradish peroxidase or cholera toxin subunit b have demonstrated that lamina I neurons project to several supraspinal areas including the thalamus, the periaqueductal gray, and the parabrachial nucleus (for reviews see Lima, D. and Coimbra, A., 1988; Spike, R. C. *et al.*, 2003; Yu, X. H. *et al.*, 2005). A comparable classification of lamina I projection neurons has been carried out in the cat (Zhang, E. T. *et al.*, 1996) and the monkey (Zhang, E. T. and Craig, A. D., 1997; Yu, X. H. *et al.*, 1999) based on the analysis of horizontal sections (Figure 5). In this latter classification, the multipolar and flattened types were merged into one category (multipolar neurons). Because of the correlation with classifications done in other species and correlation with function (see below), we have found it more appropriate to classify lamina I neurons in rat into the general types of fusiform, multipolar, and pyramidal (Yu, X. H. *et al.*, 1999; 2005; Almarestani, L. *et al.*, 2007) (Figure 6). While to a large extent these cell types can be recognized in horizontal sections (Figure 5), complete classification of these cells require a 3D reconstruction of their dendritic tree (Figures 5 and 6) (Yu, X. H. *et al.*, 1999; 2005).

5.23.4.1.2 Correspondence with function

Recent evidence suggests a correspondence between the morphological characteristics of lamina I neurons and their functional properties (Han, Z. S. *et al.*, 1998). Three main functional types of lamina I neurons

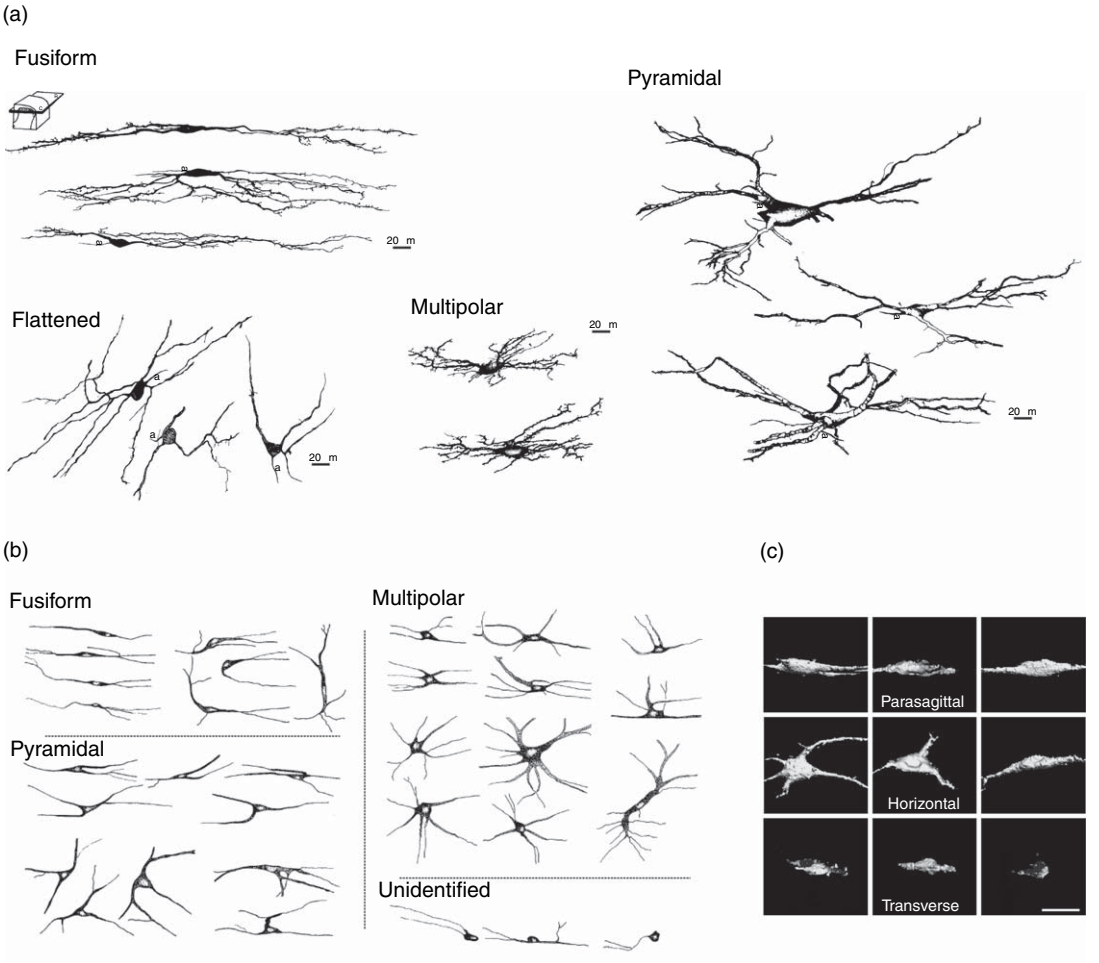

Figure 5 Representative drawings of lamina I neurons in the rat and the monkey spinal dorsal horn. The drawings in (a) are based on camera lucida reconstructions from Golgi-impregnated cells viewed in the horizontal plane (modified from Lima, D. and Coimbra, A., 1986). (b) The basic scheme was extended to higher species, such as the monkey, with minor nomenclature adjustments (modified from Zhang, E. T. and Craig, A. D., 1997; see text). (c) Three-dimensional reconstructions from serial confocal images of retrogradely labeled lamina I spinothalamic neurons in rats (from Yu, X. H. *et al.*, 2005). Note that lamina I projection neurons in rat (Yu, X. H. *et al.*, 2005), cat (Zhang, E. T. *et al.*, 1996; Han, Z. S. *et al.*, 1998), and monkey (Zhang, E. T. and Craig, A. D., 1997) do not appear to have ventrally directed dendrites (see also text) and are thus properly identified only in the horizontal plane as shown in (c) (modified from Yu, X. H. *et al.*, 2005).

have been identified on the basis of their response to cutaneous sensory inputs: nociceptive-specific (NS) neurons, responsive only to noxious heat and pinch; polymodal nociceptive neurons, responsive to noxious heat and pinch as well as to innocuous and noxious cold (HPC); and innocuous thermoreceptive neurons responsive only to innocuous cooling (COLD) (Craig, A. D. and Kniffki, A. I., 1985; Craig, A. D. and Bushnell, M. C., 1994; Dostrovsky, J. O. and Craig, A. D., 1996; Han, Z. S. *et al.*, 1998). A correspondence between these functional classes of lamina I and the morphological types (fusiform, pyramidal, and multipolar) has been found in the cat whereby fusiform cells were all NS, pyramidal cells were all COLD, and multipolar cells were divided between HPC and NS (Han, Z. S. *et al.*, 1998). These results are also consistent with previous reports that many pyramidal and multipolar cells possess large axons in the cat (Gobel, S., 1978a) and the rat (Lima, D. and Coimbra, A., 1986). In contrast, fusiform cells are characterized by thin, likely unmyelinated axons (Lima, D. and Coimbra, A., 1986), consistent with the observation that HPC and COLD cells have faster antidromic conduction velocities (Craig, A. D. and Kniffki, K. D., 1985) than NS neurons (Craig, A. D. and Kniffki, K. D., 1985). Recent evidence using

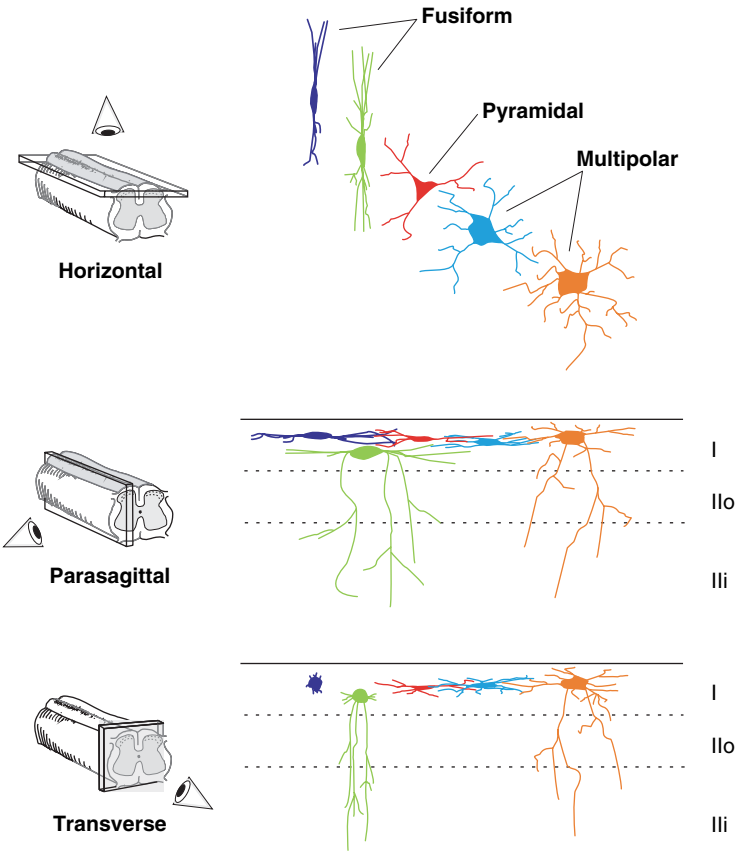

Figure 6 Morphological classification of the neuronal populations in lamina I. The classification is mainly based on cell body shape and primary dendrite orientation. Adaptation of the original classification by Lima D. and Coimbra A. (1986) to take into account recent findings on projection neurons (see Figure 5 and text) and interneurons (see text). Most cells types (especially the projection neurons) are best identified in the horizontal plane. Sagittal and transverse views may be useful to test for ventrally directed dendrites.

whole cell recording in slices indicates the presence of distinct classes of lamina I neurons on the basis of their intrinsic firing properties (Prescott, S. A. and De Koninck, Y., 2002; Ruscheweyh, R. *et al.*, 2004). In addition, a correspondence between intrinsic electrophysiological properties and morphology in lamina I has been shown in rat (Prescott, S. A. and De Koninck, Y., 2002) whereby tonic cells were typically fusiform, phasic cells were pyramidal, and delayed onset and single spike cells were multipolar. In the latter study, the multipolar cell subtype probably correspond to the small multipolar subtype with ventrally directed dendrites and therefore are likely not projection neurons.

5.23.4.1.3 Expression of NK-1r in subpopulations of lamina I neurons

The finding that pyramidal neurons corresponded to a class of lamina I neurons that only respond to innocuous thermal stimuli was of particular interest because of the evidence that nonnociceptive neurons fail to respond to SP (Henry, J. L., 1976) and do not receive significant amount of SP input (De Koninck, Y. *et al.*, 1992; Ma, W. *et al.*, 1996). We therefore decided to test whether pyramidal neurons express NK-1r (Yu, X. H. *et al.*, 1999). The results indicated that, while normally one-third of lamina I neurons are pyramidal in the cervical and lumbar enlargements of the spinal cord (Zhang, E. T. *et al.*, 1996; Zhang, E. T. and Craig, A. D., 1997; Yu, X. H. *et al.*, 1999), only ~5% of the NK-1r-expressing neurons in these areas were pyramidal, most being either fusiform or multipolar. This type of differential distribution gives further support to the concept that there is a correlation between the functional properties of neurons and their morphological features. In a recent study (Yu, X. H. *et al.*, 2005), we obtained data in the rat consistent with that in the

monkey whereby retrogradely labeled lamina I spinothalamic tract (STT) cells were evenly distributed among the three main cell types (Zhang, E. T. and Craig, A. D., 1997; Yu, X. H. *et al.*, 1999), and NK-1r immunoreactivity was also preferentially expressed in fusiform and multipolar lamina I STT neurons.

A high proportion (60–80%), but not all, of lamina I projection neurons are IR for NK-1r (Marshall, G. E. *et al.*, 1996; Yu, X. H. *et al.*, 1999; 2005). In contrast, however, only a subset of NK-1r-IR neurons are projection neurons (49% after the injection of tracer in the thalamus; Yu, X. H. *et al.*, 2005). A large proportion of lamina I neurons project to the parabrachial nucleus. Importantly, although it had been reported that very few lamina I neurons in rat project to the thalamus at lumbar levels (Spike, R. C. *et al.*, 2003), we found that a significant number, about 9%, of lamina I neurons project to the thalamus (Yu, X. H. *et al.*, 2005), a figure comparable to that found in primate by us (Yu, X. H. *et al.*, 1999) and others (Andrew, D. *et al.*, 2003). Our recent data on spinoparabrachial neurons also indicate that most pyramidal cells in this subpopulation do not express NK-1r (Almarestani, L. *et al.*, 2007).

5.23.4.2 Lamina II Neurons

Lamina II neurons have been classified originally by Ramón y Cajal (1909) into two main types, the central cell, which occurs throughout the lamina, and the limiting cell, which is restricted to a region close to the laminae I–II border. These same morphological types were identified in the cat by Gobel S. (1975; 1978b), and were renamed islet cells and stalked cells, respectively. A Golgi method study by Todd A. J. and Lewis S. G. (1986) identified cells with the characteristics of stalked and islet cells, as described by Gobel, in lamina II of the rat (Figure 7). Concerning incidence of these cells, the stalked cells were shown to represent about half of the stained cells in LIIo; in contrast, islet cells were found throughout lamina II and corresponded to about one-third of the entire stained neuronal population (Todd, A. J. and Lewis, S. G., 1986). It should be noted that these authors reported other cell types in lamina II; in fact, about half of the cells in the ventralmost part of lamina II did not fit in either the stalked or islet cell categories, although they could be subdivided into groups based on their dendritic arborization. The axons of these cells either crossed to lamina III or remained within the limits of lamina II. Some of these neurons may correspond to the stellate and laminae II–III border cells described in other species (Todd, A. J. and Lewis, S. G., 1986).

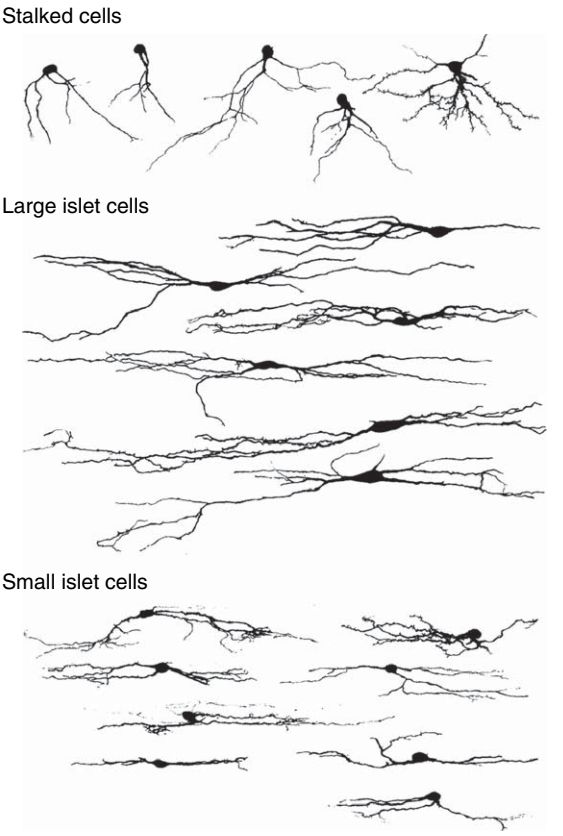

Figure 7 Representative drawings of lamina II neurons in the rat spinal dorsal horn. Three main cell types are represented in these camera lucida drawings of Golgi-impregnated cells: the stalked, small islet, and large islet cells (see text for further details). Modified from Todd A. J. and Spike R. C. (1993).

Recently, Grudt T. J. and Perl E. R. (2002) performed a detailed morphological analysis of the different cells types in lamina II following intracellular labeling in spinal cord slices of the hamster. They identified five morphological types of lamina II neurons: islet, central, medial–lateral, radial, and vertical (Figure 8). Most of lamina II neurons had dendritic arbors that were primarily orientated in the rostrocaudal dimension and relatively flattened in the mediolateral and dorsoventral directions (consistent with Scheibel, M. E. and Scheibel, A. B., 1968). The islet cells of Grudt T. J. and Perl E. R. (2002) appear to correspond well with the islet cells of Gobel S. (1975; 1978b) and the large islet cells of Todd A. J. and Lewis S. G. (1986) (Figures 7 and 8); the radial cells resembled the star-shape neurons of Bicknell H. R. and Beal J. A. (1984); or the stellate

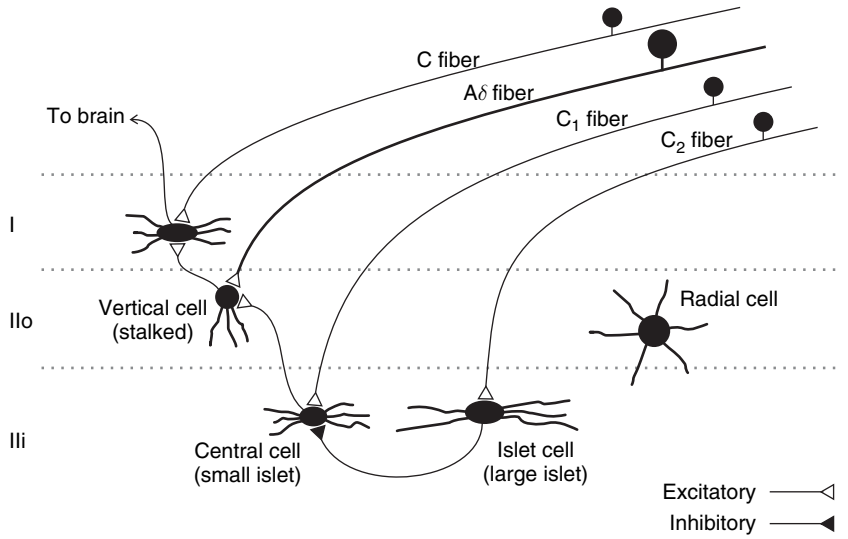

Figure 8 Diagrammatic representation of morphological types of neuron in lamina II and their primary afferent input and interconnections. A correspondence between the classification by Todd A. J. and Spike R. C. (1993) (words in parenthesis) and that of Grudt T. J. and Perl E. R. (2002) and Lu Y. and Perl E. R. (2003; 2005) is attempted as described in the text. Scheme for interconnection is based on Lu Y. and Perl E. R. (2003; 2005) (see text for a complete description). Note that distinct classes of C fibers appear to contact the two classes of islet cells based on the conduction velocity data. Note also the feed-forward inhibition between the islet cell and the central cell, which is unidirectional (Lu, Y. and Perl, E. R., 2003).

neurons described by Schoenen J. (1982). The central cells were similar to islet cells, but with a much smaller dendritic expansion in the rostrocaudal direction, thus appearing to correspond to Ramon y Cajal's central cells and Todd's small islet cells (Figures 7 and 8). The medial–lateral cells were the sole type with dendrites extending substantially in the mediolateral axis. The vertical cells appear to correspond to the limitroph neurons of Ramon y Cajal and stalked cells of Gobel.

Using paired recordings in slices and stimulation of primary afferents in rat spinal cord slices, Lu Y. and Perl E. R. (2003; 2005) were able to describe a specific connection path between subclasses of C-fiber afferents and the network of large islet cells, small islet cells (central), and stalked cells (vertical), as summarized in Figure 8. Notably, their results show that distinct subclasses of C fibers connect to different laminae II neurons subtypes and that stalked cells are indeed feed-forward excitatory cells to lamina I neurons, confirming what had been postulated in previous reports (Bennett, G. J. *et al.*, 1980; Gobel, S. *et al.*, 1980).

Concerning islet cells, it has been found that their electrophysiological properties differed depending on their localization in lamina II, as those situated in deep lamina II were nonnociceptive, while those in LIIo were nociceptive (Bennett, G. J. *et al.*, 1980; Gobel, S. *et al.*, 1980). These findings concur with previous studies in the cat by Light A. R. *et al.* (1979). It interesting to note that in the cat, according to Light A. R. and collaborators (1979), the type of response elicited from lamina II cells, either nociceptive or nonnociceptive, had little correlation with their morphology but was related to where the dendritic tree arborized. This observation was interpreted as a consequence of the type of primary sensory fibers, which contacted the dendrites of the cells, as the afferents that terminated in deep lamina II did not seem to be nociceptive in the cat (Light, A. R. and Perl, E. R., 1979).

5.23.4.3 Laminae III–VI

Laminae III–VI possess both interneurons and projection neurons and have a rather heterogeneous population of cells with dendrites that cut across these laminae (Brown, A. G., 1982). Cells of some of the major ascending pathways (spinothalamic, spinocervical, and dorsal column postsynaptic pathway) have cell bodies located in these laminae (Brown, A. G., 1982). Lamina III can be considered as a continuation of the ventralmost part of lamina II, with some small neurons with characteristics similar to those of that part of lamina II, as described in one study (Wall, P. D. *et al.*, 1979). In cat, cells in lamina

III have been described as nonnociceptive and heterogeneous (Maxwell, D. J. *et al.*, 1983) based on intracellular injections of physiologically characterized neurons. However, this concept that all lamina III cells are nonnociceptive is not correct based on the detection of wide dynamic range cells in this laminae III–IV of the cat, which possess dorsally oriented dendrites branching in the superficial laminae (De Koninck, Y. *et al.*, 1992; Ribeiro-da-Silva, A. *et al.*, 1992; Ma, W. *et al.*, 1996; 1997), as well as on the detection of neurons in the same laminae of the rat, which express the NK-1r and possess dorsally oriented dendrites that branch into laminae I and II (Liu, H. *et al.*, 1994a; Brown, J. L. *et al.*, 1995; Littlewood, N. K. *et al.*, 1995; Naim, M. *et al.*, 1997).

5.23.4.4 Neurochemistry of Dorsal Horn Neurons

In spite of a large number of studies that identified neurochemicals in dorsal horn neurons, the available information is less than satisfactory because, with a few exceptions, the information on the morphological properties of the neurons is either incomplete or simply lacking. This is a consequence of the fact that, in most cases, little more is known than the size and the localization of the neurochemically characterized cell bodies. There are some exceptions, however. The most striking exception is likely the excellent characterization of the population that expresses the NK-1r because a Golgi-like staining of the cells is obtained. With most neurochemicals, either the staining is inadequate to allow a proper characterization of the cell (e.g., cell body faintly labeled) or the number of immunolabeled cells is so high that it is impossible to characterize individual cells. In the case of *in situ* hybridization studies, only cell bodies are labeled, and therefore the information obtained with the use of this approach is significant but limited. The only approaches that can deliver an integrative view of morphological and neurochemical properties of the cells are those that involve the combination of intracellular filling of neurons with immunocytochemistry, but they have been sparsely used to date. Therefore, in the text below little correlation to cell populations described above will be made because such data are simply lacking. Table 1 gives an overview of classical transmitter/neuropeptide colocalizations in the dorsal horn, as described in the text.

5.23.4.4.1 Neurokinins

All three main mammalian neurokinins (SP, neurokinin A, and neurokinin B (NKB)) occur in dorsal horn neurons. SP-containing cell bodies have been detected in laminae I and II, both with immunocytochemistry (Ljungdahl, A. *et al.*, 1978; Ribeiro-da-Silva, A. *et al.*, 1991) and *in situ* hybridization (Warden, M. K. and Young, W. S., 1988). It is interesting to note that most, if not all, SP-IR cell bodies in the rat dorsal horn colocalize enkephalin (ENK) immunoreactivity (Ribeiro-da-Silva, A. *et al.*, 1991), and they seem to be glutamatergic as well because they express the vesicular glutamate transporter 2 (VGLUT2) (Todd, A. J. *et al.*, 2003). It has been speculated in the past that some of these neurons colocalizing SP and enkephalin immunoreactivities represent stalked cells, based on their laminar localization in LIIo, absence of presynaptic dendrites, and synapses on lamina I neurons (Ribeiro-da-Silva, A. *et al.*, 1991). However, neurons colocalizing SP and enkephalin likely belong to other cell types as well and some of these project to higher levels. In particular, SP-IR lamina I and lamina V cells have been shown to project to the thalamus in rat and cat (Battaglia, G. and Rustioni, A., 1992), and it is possible that they also project to other targets such as the midbrain parabrachial nucleus. Based on the finding that spinal cord SP-IR neurons normally colocalize enkephalin and glutamate, we can speculate that such projection neurons colocalize all three neurochemicals.

Virtually all SP-containing neurons in the rat express neurokinin A (NKA) as well (Carter, M. S. and Krause, J. E., 1990), which means that their distribution is essentially the same. This applies to the primary sensory fibers that also express SP, which represent the main source of SP in the dorsal horn (see Section Types of Afferents, Neurochemistry, and Termination in Spinal Cord). Another source of SP and NKA in the dorsal horn are axons originating from cell bodies located in the brain stem (Hökfelt, T. *et al.*, 1978; Gilbert, R. F. *et al.*, 1982); although most such fibers terminate in the ventral horn, some terminate in the dorsal horn.

NKB derives from a different precursor, and in contrast to SP and NKA, does not occur in primary sensory neurons (Ogawa, T. *et al.*, 1985). A light and electron microscopic immunocytochemical study using a marker of NKB neurons revealed that the signal occurs in axon terminals in laminae I–II, with a peak in lamina IIi, and in cell bodies and dendrites mostly in lamina IIi (McLeod, A. L. *et al.*, 2000).

Lamina III showed much less immunolabeling. Signal for NKB was detected in dendrites of type I glomeruli, suggesting a participation in the modulation of nociception (McLeod, A. L. *et al.*, 2000). Neurons expressing NKB seem to be excitatory and glutamatergic (Polgár, E. *et al.*, 2006).

5.23.4.4.2 Neurokinin receptors

Originally, NK-1r immunoreactivity was described in neurons with cell bodies residing in lamina I and in laminae III–IV, but not in lamina II (Liu, H. *et al.*, 1994a; Nakaya, Y. *et al.*, 1994). More recent studies, however, have identified NK-1r immunoreactivity in some neurons in LIIo (McLeod, A.L. *et al.*, 1998; Ribeiro-da-Silva, A. *et al.*, 2000). Most of the NK-1r-IR neurons project to higher levels, having targets such as the thalamus (Marshall, G. E. *et al.*, 1996), the parabrachial nucleus (Ding, Y.-Q. *et al.*, 1995; Todd, A. J. *et al.*, 2000), the lateral reticular nucleus, the dorsal part of caudal medulla, and, to a minor extent, the periaqueductal gray (Todd, A. J. *et al.*, 2000).

The receptor for neurokinin A (the neurokinin-2 receptor) hardly occurs in the CNS (for review see Ribeiro-da-Silva, A. *et al.*, 2000). Immunoreactivity for the neurokinin-2 receptor in the superficial spinal dorsal horn was rather weak and restricted to a narrow band in the lateral part of lamina I, and seemed to be localized in glial cells (Zerari, F. *et al.*, 1998). This is an unexpected finding that indicates that either neurokinin A acts through another receptor in the CNS or that it acts mainly in the periphery. There is evidence that NKA coreleased with SP from primary sensory fibers acts through the NK-1r and may be an important component of signaling through peptidergic afferent fibers (Trafton, J. A. *et al.*, 2001).

The preferential receptor for NKB, the neurokinin-3 receptor, was identified in cell bodies located in lamina I and, mostly, in lamina II (Ding, Y. Q. *et al.*, 1996; Zerari, F. *et al.*, 1997; Mileusnic, D. *et al.*, 1999; Ding, Y. Q. *et al.*, 2002). Interestingly, the cell populations that express the neurokinin-3 receptor coexpress either the μ-opioid receptor or GABA and nitric oxide synthase (NOS) (Ding, Y. Q. *et al.*, 2002).

5.23.4.4.3 CGRP and CGRP receptors

Immunoreactivity for CGRP in the spinal dorsal horn is restricted to primary sensory fibers in rodents, and likely in others species as well. Concerning CGRP receptors, their distribution has been studied with ligand binding and have been shown to occur in high density in lamina I and in deeper laminae but were sparse in lamina II (Yashpal, K. *et al.*, 1992). Curiously, following peripheral nerve lesion, CGRP receptors were upregulated in lamina II, indicating that lamina II cells have the capacity to synthesize the receptor (Kar, S. *et al.*, 1994).

5.23.4.4.4 Somatostatin

The neuropeptide SOM occurs both in primary sensory fibers (see above) and in dorsal horn neurons (Hökfelt, T. *et al.*, 1976; Alvarez, F. J. and Priestley, J. V., 1990; Ribeiro-da-Silva, A. and Cuello, A. C., 1990b). Cells bodies from SOM-IR neurons occur mainly in lamina II (Alvarez, F. J. and Priestley, J. V., 1990; Ribeiro-da-Silva, A. and Cuello, A. C., 1990b) and seem to be glutamatergic as they also express VGLUT2 (Todd, A. J. *et al.*, 2003). The receptors for SOM are G protein-coupled and form a family of five receptors (sst1 to sst5) (Dournaud, P. *et al.*, 2000). The distribution of these receptor subtypes has been studied with immunocytochemistry, and they have been found in cell bodies and processes in the superficial dorsal horn (Schulz, S. *et al.*, 1998; Von Banchet, G. S. *et al.*, 1999).

5.23.4.4.5 Opioid peptides

5.23.4.4.5.(i) Enkephalins Although there are two main enkephalins, met- and leu-enkephalin, no differences in distribution have been detected with antibodies generated against each of the two, and as they share a common precursor, *in situ* hybridization studies do not reveal differences in distribution either. Therefore, as in most studies, we refer to enkephalin immunoreactivity, not discriminating whether studies were done with antibodies raised against leu- or met-enkephalin. Enkephalin immunoreactivity is intense in axons and cell processes in laminae I and II (Hökfelt, T. *et al.*, 1977; Hunt, S. P. *et al.*, 1981) and has also been detected in neuronal cell bodies in laminae I–III (Del Fiacco, M. and Cuello, A. C., 1980; Hunt, S. P. *et al.*, 1981; Miller and Seybold, 1989). *In situ* hybridization studies have not detected any significant evidence for the presence of the enkephalin precursor signal in DRG neurons, beyond a few isolated cells (Ruda, M. A. *et al.*, 1989), and sensory deafferentation does not result in any decrease of enkephalin levels in the dorsal horn (Ruda, M. A. *et al.*, 1986). Therefore, almost all the enkephalin in the dorsal horn seems to be from local circuit neurons, with a minor component colocalized in axons from serotonergic neurons of the raphe nuclei that project to the spinal cord (Hökfelt, T. *et al.*, 1979); most such axons,

however, terminate in the ventral horn (Tashiro, T. *et al*., 1988; Menétrey, D. and Basbaum, A. I., 1987). A small percentage of enkephalinergic neurons project to the brain (Standaert, D. G. *et al*., 1986). Concerning enkephalin in neurons with cell bodies located in the dorsal horn, it occurs in two different populations of neurons: (a) cells that are SP-IR (Tashiro, T. *et al*., 1987; Senba, E. *et al*., 1988; Ribeiro-da-Silva, A. *et al*., 1991) and that likely are glutamatergic (Todd, A. J. *et al*., 2003); and (b) cells that are GABAergic (Todd, A. J. *et al*., 1992b). An interesting conclusion is that as all SP-IR neurons in the dorsal horn seem to possess enkephalin immunoreactivity, the colocalization of both peptides can be used as a marker to identify SP-IR fibers that are intrinsic to the dorsal horn (Ribeiro-da-Silva, A., 2004). The ultrastructural studies of SP and enkephalin double labeling have confirmed the colocalization of the two peptides in both rat and cat and provided evidence that enkephalin-IR boutons or presynaptic dendrites are never presynaptic to SP-IR boutons (Ribeiro-da-Silva, A. *et al*., 1991; Ma, W. *et al*., 1997). In the cat, enkephalin-IR boutons have been shown to contact spinothalamic neurons (Ruda, M. A. *et al*., 1984) and neurons of the dorsal column postsynaptic pathway (Nishikawa, N. *et al*., 1983). Our own data on physiologically characterized, intracellularly filled dorsal horn neurons, some of which likely projected to the brain, has shown that these cells had appositions from boutons colocalizing SP and enkephalin immunoreactivities and from boutons IR for only one of the peptides, which likely represented the population colocalizing enkephalin and GABA and the population colocalizing SP and CGRP (primary sensory in origin) (Ma, W. *et al*., 1997).

5.23.4.4.5.(ii) Dynorphins Most of the dynorphin in the dorsal horn is from spinal cord neurons, with a minor component at sacral levels from visceral afferents (see above). The distribution of the dynorphins in the dorsal horn has been studied both by immunocytochemistry with antibodies raised against dynorphin A and dynorphin B as well as by *in situ* hybridization using probes for the dynorphin precursor. The available data indicate that the dynorphins occur in axons and cells bodies in laminae I, IIo, and V, in both rat and cat (Cruz, L. and Basbaum, A. I., 1985; Miller, K. E. and Seybold, V. S., 1987; Leah, J. *et al*., 1988; Ruda, M. A. *et al*., 1988; Cho, H. J and Basbaum, A. I., 1989). These neurons have been reported as forming an heterogeneous population, although some neurons in LIIo resembled stalked cells (Cruz, L. and Basbaum, A. I., 1985; Cho, H. J. and Basbaum, A. I., 1989). The dynorphins are not restricted to local circuits neurons, as some of the neurons that express them project to the parabrachial nucleus (Standaert, D. G. *et al*., 1986).

5.23.4.4.5.(iii) Endormorphins Of the two endomorphins, endomorphin-2 is restricted to primary sensory fibers, where it is colocalized with SP (Martin-Schild, S. *et al*., 1998; Sanderson Nydahl K., *et al*., 2004). In contrast, endomorphin-1 is intrinsic to the CNS and occurs in fibers in laminae I and II (Martin-Schild, S. *et al*., 1999).

5.23.4.4.6 Opioid receptors

Besides occurring on primary sensory fibers (see above), opioid receptors are located on dorsal horn neurons as well. *In situ* hybridization cytochemistry has confirmed the occurrence of opioid receptors in dorsal horn neurons (Minami, M. and Satoh, M., 1995). The δ-opioid receptor occurs both on cell bodies and dendrites of dorsal horn neurons and in axon terminals (Cheng, P. Y. *et al*., 1995; 1997); some of the axon terminals expressing the receptor colocalize enkephalin (Cheng, P. Y. *et al*., 1995). In contrast, the κ receptor has been localized mostly in dendrites and cell bodies (Arvidsson, U. *et al*., 1995). Immunoreactivity for the μ receptor occurs mostly in lamina II (Honda, C. N. and Arvidsson, U., 1995; Kemp, T. *et al*., 1996), axon terminals, dendritic profiles, and cell bodies (Cheng, P. Y. *et al*., 1996; 1997). Most of the cell bodies displaying μ-opioid receptor immunoreactivity are located in lamina II and do not colocalize GABA or glycine immunoreactivities, which suggests that the neurons that express the μ receptor may be mostly excitatory interneurons (Kemp, T. *et al*., 1996).

5.23.4.4.7 Glutamate

It has been known for a long time that a high percentage of neurons in the dorsal horn are glutamatergic. However, the evidence was mostly indirect, as glutamate immunostaining is not a reliable marker of glutamatergic cells bodies (Ottersen, O. P. and Storm-Mathisen, J., 1984). Currently, the most reliable way of identifying glutamatergic dorsal horn neurons is the immunocytochemical detection of one of the vesicular glutamate transporters. However, because the immunoreactivity is located mostly in axonal terminals and is low in dendrites and cell bodies, we have to rely on colocalization studies to identify the glutamatergic neurons.

Colocalization studies have revealed that most non-primary sensory axonal varicosities in the dorsal horn that expressed SP, SOM, or neurotensin were IR for the vesicular glutamate transporter (VGLUT2), strongly indicating that these cell populations are glutamatergic (Todd, A. J. *et al.*, 2003). It is also assumed that most of the projection neurons, including the cells of lamina I, are glutamatergic, although direct immunocytochemical evidence is lacking. Systematic studies combining *in situ* hybridization for vesicular glutamate transporters are required to confirm this point.

5.23.4.4.8 Glutamate receptors

Besides occurring in primary sensory fibers (see section Receptors on Primary Sensory Fibers above), glutamate receptors have also been identified in dorsal horn neurons. Concerning the ionotropic glutamate receptors, their distribution has been studied with both *in situ* hybridization and immunocytochemistry. The predominant subunits of AMPA receptors in the dorsal horn are GluR1 and GluR2 (Furuyama, T. *et al.*, 1993; Jakowec, M. W. *et al.*, 1995a; 1995b), and the labeling of many cell bodies has been detected by immunocytochemistry. An interesting observation is that the GluR1 subunit is particularly associated with GABAergic neurons, while the GluR2 is mainly found in cells that lack GABA (Spike, R. C. *et al.*, 1998). Concerning NMDA receptors, the NR1 subunit is highly expressed in dorsal horn neurons (Tölle, T. R. *et al.*, 1993; Watanabe, M. *et al.*, 1994) and may be expressed by all cells. Less is known about the expression of the NR2 subunit of the NMDA receptor and of kainate receptors (Furuyama, T. *et al.*, 1993; Tölle, T. R. *et al.*, 1993; Watanabe, M. *et al.*, 1994). Metabotropic glutamate receptors are also expressed by dorsal horn neurons and of these the mGluR5 is the most prevalent (Berthele, A. *et al.*, 1999; Jia, H. *et al.*, 1999).

5.23.4.4.9 Inhibitory amino acids

5.23.4.4.9.(i) GABA The distribution of GABAergic neurons in the dorsal horn was originally studied by autoradiography using ^{3}H-GABA high-affinity uptake and by immunocytochemistry using anti-glutamic acid decarboxylase (GAD) antibodies (Ribeiro-da-Silva, A. and Coimbra, A., 1980; Hunt, S. P. *et al.*, 1981; Barber, R. P. *et al.*, 1982). Later studies used immunoreactivity for GABA itself (Todd, A. J. and McKenzie, J., 1989). A study in rat showed that GABAergic neurons were evenly distributed in laminae I–III, where they represented 24–33% or 28–46% of the overall neuronal population (Todd, A. J. and McKenzie, J., 1989; Todd, A. J. and Sullivan, A. C., 1990). Through a combination of GABA immunostaining and the Golgi method, some of the GABAergic neurons of lamina II were identified as islet cells, but never as stalked cells (Todd, A. J. and McKenzie, J., 1989). This observation is consistent with the observation of islet cells with presynaptic dendrites (Gobel, S. *et al.*, 1980; Spike, R. C. and Todd, A. J., 1992), which indicate an inhibitory function. Results from Lu Y. and Perl E. R. (2003; 2005) suggest that only the large islet cells of Todd A. J. (1986) (Figures 7 and 8) are GABAergic while small islet cells (central cell) are glutamatergic. Large islet cells appear to act as feed-forward inhibitory neurons to small islet cells (Lu, Y. and Perl, E. R., 2003) (Figure 8).

In the spinal cord, GABA participates in both presynaptic inhibition on terminals of primary afferents and postsynaptic inhibition of dorsal horn neurons. Morphological support for the involvement of GABAergic interneurons in presynaptic inhibition was obtained by demonstrating that these are presynaptic to primary sensory fibers; this evidence was obtained by means of a combination of GAD immunocytochemistry with nerve lesions in the rat (Barber, R. P. *et al.*, 1978) or with the intracellular filling of identified afferent fibers in the cat (Maxwell, D. J. and Noble, R., 1987). The identification of both presynaptic dendrites and peripheral axons in glomeruli presynaptic to their central bouton, of known primary sensory origin, provided further morphological support to the participation of GABAergic dorsal horn neurons in the presynaptic inhibition of primary sensory fibers (Todd, A. J., 1996; Ribeiro-da-Silva, A., 2004). In these presynaptic structures, GABA is colocalized with other neurochemicals, such as enkephalin, acetylcholine (Ribeiro-da-Silva, A., 2004), glycine (Todd, A. J., 1991; 1996), NPY, or galanin (Polgár, E. *et al.*, 1999b). A minor component of the GABAergic terminals in the dorsal horn originates from the brain stem (Antal, M. *et al.*, 1996), and a recent *in vivo* electrophysiological study provides evidence for descending monosynaptic GABAergic and/or glycinergic inputs from the rostral ventromedial medulla to the substantia gelatinosa (Kato, G. *et al.*, 2006).

5.23.4.4.9.(ii) Glycine Glycinergic neurons are found in most laminae of the dorsal horn; in laminae I–III, their proportion in the overall is considerably higher in lamina III (30%) than in lamina I (9%) or in

lamina II (14%) (Todd, A. J. and Sullivan, A. C., 1990). Virtually all glycinergic neurons in laminae I–III are also GABAergic (Todd, A. J. and Sullivan, A. C., 1990; Todd, A. J., 1991); however, only about half of the GABAergic cells colocalize glycine immunoreactivity (Todd, A. J. and Sullivan, A. C., 1990; Todd, A. J., 1991). Terminals colocalizing GABA and glycine immunoreactivities are presynaptic mostly to dendrites and cell bodies, except in LIIi and deeper dorsal horn where they are also presynaptic to primary sensory fibers in type II but not in type I glomeruli (Todd, A. J., 1996). There is indirect evidence that glycine is likely colocalized with GABA in some descending fibers from the brain stem (Kato, G. *et al.*, 2006).

5.23.4.4.10 GABA and glycine receptors

$GABA_A$ receptors seem to be ubiquitous in dorsal horn neurons, where their subunit precursors have been identified by *in situ* hybridization (Persohn, E. *et al.*, 1991) and their proteins by immunocytochemistry (Alvarez, F. J. *et al.*, 1996; Bohlhalter, S. *et al.*, 1996). The combination of $\alpha 3$, $\beta 3$, and $\gamma 2$ subunits appears to occur in cells throughout the dorsal horn, while $\alpha 1$ subunits are expressed by neurons in deeper laminae (Bohlhalter, S. *et al.*, 1996). An electron microscopic study using an antibody-recognizing subunits $\beta 2$–$\beta 3$ of the $GABA_A$ receptor revealed predominantly dendrite and cell body staining, with no direct evidence of labeling of sensory fibers (Alvarez, F. J. *et al.*, 1996).

A study of the distribution of immunoreactivity for the two subunits of the metabotropic $GABA_B$ receptor, $GABA_BR1$ and $GABA_BR2$, revealed that they occurred in highest concentrations in laminae I and II, where they were detected both in cell bodies and in the neuropile (Margeta-Mitrovic, M. *et al.*, 1999). The localization of the cell bodies that express the subunits of the $GABA_B$ receptor was confirmed by *in situ* hybridization (Towers, S. *et al.*, 2000).

Interestingly, in the dorsal horn, glycine receptors seem restricted to intrinsic neurons. Glycine receptors are ionotropic receptors made up of a combination of α and β subunits. The initial studies were performed with antibodies against gephyrin (a glycine- and GABA receptor-associated protein). These studies were performed at the time when it was thought that this protein was associated only with the glycine receptor. Surprisingly, these studies were rather accurate, as in the spinal cord, gephyrin-IR sites match the distribution of glycine receptors more closely than that of $GABA_A$ receptors (see e.g. Mitchell, K. *et al.*, 1993). One of the glycine receptor subunits (GlyR $\alpha 3$) has been found to be specifically expressed in the superficial laminae of the spinal dorsal horn, particularly in lamina II (Harvey, R. J. *et al.*, 2004), although the most abundant subunit in the adult spinal cord is the $\alpha 1$ (Becker, C. M. *et al.*, 1988). One interesting feature relative to the distribution of GABA and glycine receptors in the spinal cord is that many synapses colocalize GABA and glycine, and the specificity of the mixed GABA/glycine synapses seems to be determined by the expression, properties, and the subsynaptic localization of the $GABA_A$, $GABA_B$, and glycine receptors in the target cells (Chéry, N. and De Koninck, Y., 1999; 2000) and their changes during development (Keller, A. F. *et al.*, 2001).

It should be kept in mind that the great majority of GABA- and glycine-containing terminals are presynaptic to spinal neurons, not to primary afferent terminals (Todd, A. J. and Spike, R. C., 1993), and GABAergic and glycinergic interneurons control an important network of polysynaptic connections between primary afferents and dorsal horn neurons. For example, blockade of GABAergic and glycinergic inhibition unmasks low-threshold input to dorsal horn neurons that do not receive monosynaptic input from low-threshold afferents (Baba, H. *et al.*, 2003; Torsney, C. and MacDermott, A. B., 2006). Impaired inhibition is thus a likely substrate for cross talk between sensory modalities and appear to underlie allodynia characteristic of neuropathic pain syndromes (Moore, K. A. *et al.*, 2002; Coull, J. A. *et al.*, 2003; Coull, J. A. *et al.*, 2005).

5.23.4.4.11 Other classical transmitters and other neuropeptides

One of the better-defined transmitter-specific systems in the dorsal horn is the cholinergic one. In fact, neuronal perikarya IR for choline acetyltransferase (ChAT) have been identified in the spinal dorsal horn (Kimura, H. *et al.*, 1981; Barber, R. P. *et al.*, 1984; Todd, A. J., 1991). These neurons are not numerous, occur mainly in laminae III–IV, and are presynaptic to primary sensory fibers in synaptic glomeruli and to neurons (Ribeiro-da-Silva, A. and Cuello, A. C., 1990a). Interestingly, as mentioned above, most, if not all, of these cholinergic cell bodies and boutons colocalize GABA.

Regarding other transmitters, spinal serotonin originates from neurons with cell bodies in the brain stem (for review see Ruda, M. A. *et al.*, 1986). Interestingly, in the cat, these serotonin-IR profiles

have been shown to synapse on projection neurons (Ruda, M. A., 1986). These fibers colocalizes other transmitters such as enkephalin (Hökfelt, T. *et al.*, 1979) (see above) or SP and thyrotropin-releasing hormone (TRH) (Johansson, O. *et al.*, 1981). Another transmitter-specific system originating from the brain stem is the noradrenergic one. Although their light microscopic distribution and their origin in the brain stem are well known (Westlund, K. N. *et al.*, 1983; Fritschy, J. M. and Grzanna, R., 1990), there is still not much information about these noradrenergic fibers except that they are presynaptic to spinal dorsal horn neurons (Hagihira, S. *et al.*, 1990; Doyle, C. A. and Maxwell, D. J., 1991). Interestingly, noradrenergic analgesia appears to involve presynaptic inhibition of glutamate release from α2c-adrenergic terminals of local excitatory interneurons (Olave, M. J. and Maxwell, D. J., 2002; 2003a) contacting NK-1r-IR projection neurons (Olave, M. J. and Maxwell, D. J., 2003b). Neurotensin immunoreactivity occurs in neurons in laminae I and II (Hunt, S. P. *et al.*, 1981; Seybold, V. S. and Elde, R. P., 1982), which do not colocalize GABA (Todd, A. J. *et al.*, 1992a) but do express VGLUT2, and are likely glutamatergic (Todd, A. J. *et al.*, 2003). Furthermore, most of the neurotensin-IR neurons in LIIi express protein kinase C gamma (Polgár, E. *et al.*, 1999a).

5.23.5 Identified Neuronal Circuits

While our knowledge of synaptic circuits in the dorsal horn remains limited, some patterns are emerging based on recent findings. Figure 9 attempts to summarize some observations described above. It should be noted here that there are significant interspecies differences in the neurochemical and anatomical organization of the region. Thus some of the proposed circuits may not hold across all species.

One should stress here that, while we propose well-defined circuits, not all chemical communication involves hard-wired synapses (Zoli, M. *et al.*, 1999). Nonsynaptic or paracrine transmission is thought to occur particularly with peptides and monoamines; however, it probably occurs for amino acid transmitters also acting both on their ionotropic and metabotropic receptors (Rossi, D. and Hamann, M., 1998; Chéry, N. and De Koninck, Y., 1999; 2000). Whereas under physiological conditions, most interneuronal communication in the dorsal horn probably takes place either at synapses or close to the site of release, diffusion of neurochemicals over longer distances cannot be excluded, particularly in the case of neuropeptides. Nevertheless, it should be kept in mind that the neuropile represents a significant diffusion barrier, and it is unlikely that even peptides diffuse large distances when released at physiological concentrations. Therefore, a detailed description of the chemical neuroanatomy of the dorsal horn circuits is important to understand sensory processing.

As most synapses in the dorsal horn are axodendritic, it is not surprising that the majority of interneurons appear to act on their targets through a postsynaptic mechanism; however, some cells clearly participate in presynaptic interactions. GABAergic axons, which are thought to originate from local interneurons, establish axoaxonic synapses on the central boutons of synaptic glomeruli, except for those in peptidergic (type Ib) glomeruli that are seldom postsynaptic to other profiles. There is a fundamental difference between the types of GABAergic neurons that innervate type Ia and type II glomeruli, because boutons containing GABA and glycine are presynaptic to the central boutons of type II, but not to type Ia glomeruli (Todd, A. J., 1996). In contrast, neurons colocalizing GABA and enkephalin immunoreactivities seem to innervate central axons of type I and II glomeruli equally (through both axoaxonic and dendroaxonic synapses) (Ribeiro-da-Silva, A., 2004). The population of neurons with GABA and ChAT is relatively small (Todd, A. J., 1991); however, their axons contribute a significant contingent of axoaxonic synapses in type II, and to a lesser extent in type Ia, glomeruli (Ribeiro-da-Silva, A. and Cuello, A. C., 1990a; Ribeiro-da-Silva, A., 2004). The neurons with GABA and acetylcholine (revealed by ChAT immunoreactivity) have cell bodies in laminae III and IV and dendrites that extend superficially, where they receive synaptic input from primary afferents in both type Ia and type II glomeruli. Cells that colocalize GABA and NPY appear to selectively target NK-1r-IR laminae III/IV projection neurons, with which they make numerous axodendritic and axosomatic synapses (Polgár, E. *et al.*, 1999b).

As discussed above, most (if not all) of the SP-containing neurons in the superficial laminae are also enkephalin-IR (Ribeiro-da-Silva, A. *et al.*, 1991). They are located in laminae I and II and receive synaptic input from nonpeptidergic C fibers in type Ia glomeruli and from SP-containing afferents outside glomeruli. Interestingly, based on evidence

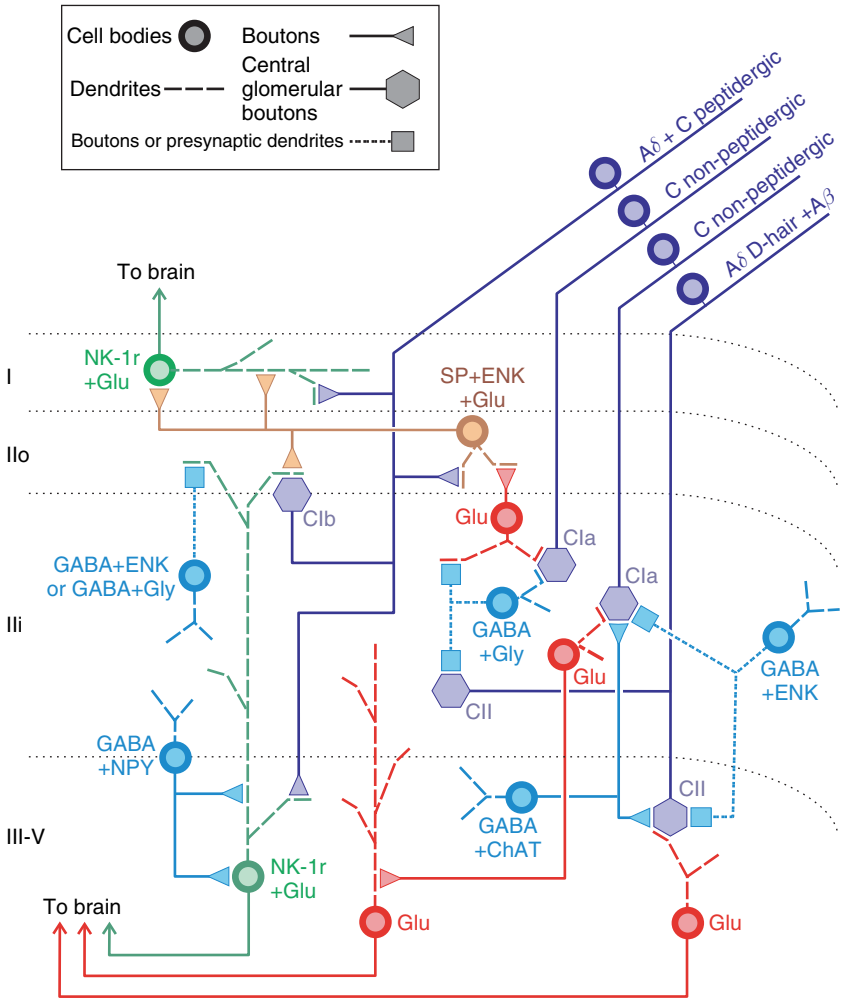

Figure 9 Summary diagram of neuronal circuits in the dorsal horn. Different synaptic arrangements involve the different classes of primary afferents endings in the dorsal horn (glomerular and nonglomerular). In particular, the glomerular structures are exquisite sites of presynaptic modulation of afferent inputs. Yet, it should be kept in mind that, while this diagram highlights the different presynaptic arrangements in which the different populations of GABAergic interneurons are involved, most GABAergic and glycinergic synapses remain axodendritic and axosomatic in the dorsal horn. While physiological studies indicate that Aδ high-threshold mechanoreceptors (HTM) provide input to laminae I and V, further information on the synaptic arrangements they are involved in is unavailable due to the lack of specific markers for these types of afferents. Peptidergic Aδ and C nociceptors are known to contact spinal projection neurons that express the NK-1 receptor both in laminae I and V. The substance P (SP)–enkephalin (ENK)–Glu interneuron positioned in lamina IIo represents a prototype stalked cell, which, for the sake of simplicity, accounts for both the circuitry illustrated in Figure 8 based on the physiological data (see Lu, Y. and Perl, E. R., 2003; 2005) and that based on what is known of the peptidergic circuitry (Ribeiro-da-Silva, A. *et al.*, 1991). It remains to be confirmed, however, whether a single type of stalked cell, expressing SP, ENK, and glutamate, constitutes a common pathway to lamina I projection neurons or whether parallel circuits are involved. Two nonpeptidergic afferent pathways are illustrated to account for the possibility that parallel circuits with no cross talk at the level of the dorsal horn may connect to ascending pathways (see text for further details; Braz, J. M. *et al.*, 2005).

from studies in the cat (Ma, W. *et al.*, 1997), these neurons seem to preferentially innervate nociceptive neurons in lamina I and in the deep dorsal horn, which probably express the NK-1r (Figure 9).

Finally, these findings, together with those of Lu Y. and Perl E. R. (2003; 2005) and the evidence of a parallel pathway via laminae II–V (Braz, J. M. *et al.*, 2005) (see above) that exclude NK-1r-expressing cells, suggest that distinct subclasses of nonpeptidergic afferents connect to laminae I and V ascending pathways with virtually no cross talk at the level of the dorsal horn (Figure 9).

5.23.6 Conclusion and Future Directions

An important conclusion of this review is that, despite all the progress, we are still unable to answer a few very basic questions regarding the synaptic organization of the dorsal horn. This is in part a consequence of the heterogeneity of neuronal populations in each layer and therefore the difficulty to properly identify subtypes of neurons in functional studies (in contrast with highly organized structures like the cerebellum, hippocampus, and even neocortex).

For example, while a significant amount of data on the organization of inhibitory circuits is available from purely morphological and immunocytochemical studies, little is known at the functional level, in part because of the difficulty to identify GABAergic and glycinergic interneurons for targeted electrophysiological recording. This is likely to change, thanks to the growing availability of transgenic mice that express enhanced green fluorescent protein (GFP) in specific subpopulations of inhibitory interneurons (e.g., under the control of the promoter for glutamic acid decarboxylase or the glycine transporter 2) (Hantman, A. W. *et al.*, 2004; Heinke, B. *et al.*, 2004; Dougherty, K. J. *et al.*, 2005; Zeilhofer, H. U. *et al.*, 2005). The same is true for subpopulations of interneurons that are associated with other specific markers (e.g., neuropeptides and calbindin).

Emerging classification schemes, based on combinations of morphological features, transmitter and receptor phenotypes, and electrophysiological properties (Thomson, A. M. *et al.*, 1989; Yoshimura, M. and Jessell, T. M. 1989; Lopez-Garcia, J. A. and King, A. E., 1994; Han, Z. S. *et al.*, 1998; Jo, Y. H. *et al.*, 1998; Yu, X. H. *et al.*, 1999; Grudt, T. J. and Perl, E. R., 2002; Prescott, S. A. and De Koninck, Y., 2002; Ruscheweyh, R. and Sandkuhler, J., 2002; Ruscheweyh, R. *et al.*, 2004; Hantman, A. W. and Perl, E. R., 2005; Yu, X. H. *et al.*, 2005), will also be critical to better understand the organization of neuronal circuits in the dorsal horn. Indeed, studies combining electrophysiological recording and intracellular labeling with immunocytochemistry remain critical to obtain a finer identification of neuronal subpopulations and their function as well as to obtain a more complete picture of the afferent and efferent connections of transmitter-specific interneurons; however, such approaches are technically demanding and remain insufficiently used (De Koninck, Y. *et al.*, 1992; Ribeiro-da-Silva, A. *et al.*, 1992; Ma, W. *et al.*, 1996; 1997; Lawson, S. N. *et al.*, 1997; 2002).

An important challenge for the future will also be to better unravel the functional significance of the multiple transmitter signals originating from the same cells and the same synaptic terminals. For example, the functional meaning of the corelease of GABA and glycine (Chéry, N. and De Koninck, Y., 1999) – two very similar neurotransmitters – from the same terminals remains elusive in a large part. Several synapses also appear to use opposing transmitters, such as SP and enkephalin (Ribeiro-da-Silva, A. *et al.*, 1991) or GABA and ATP (Jo, Y. H. and Schlichter, R., 1999); whether these involve local feedback systems, differential release conditions, or nonlinear modes of action (Kupfermann, I., 1991; Nusbaum, M. P. *et al.*, 2001) remains to be determined. Several of these questions continue to be elusive simply because the modes of action of several neuropeptides remain incompletely understood. Target-selective expression of receptors may determine the functional meaning of the mixed transmitter signals released from the same neuron. For example, when GABA and glycine are colocalized in axoaxonic contacts with primary afferent terminals, only $GABA_A$ and $GABA_B$ are expressed on those terminals; the glycinergic signal must only be meaningful at other synapses from the same presynaptic neuron or acting on receptors located on dendrites neighboring the release site (Rossi, D. and Hamann, M., 1998). In the same line, fine subcellular segregation of receptors in the target cells may have very significant impact on how mixed transmitter signals are decoded by the postsynaptic cell (see e.g., Chéry, N. and De Koninck, Y., 1999; 2000; Keller, A. F. *et al.*, 2001).

While important information has arisen from the use of markers of specific primary afferent subclasses, it is necessary to develop more refined classification schemes. For example, both on anatomical and physiological grounds, the current classification schemes of peptidergic and nonpeptidergic C-fiber afferents (e.g., binding IB4 or expressing CGRP) remains too general to account for the existing diversity of subclasses. The search for newer cell surface markers or the development of transgenic models expressing GFP in specific subpopulations of cells will be important to unravel the synaptic circuitry and functional role of each subclass of afferents and their spinal dorsal horn targets.

An important issue to keep in mind that may be an important limitation in our current understanding is the occurrence of interspecies differences. For

example, many of the original studies on neurons characterized physiologically and labeled intracellularly with injections of markers have been performed in the cat, whereas tract-tracing and immunocytochemical studies have generally been carried out in the rat and the monkey, while studies relying on transgenic tools have to be conducted in the mouse. Many of these species differences have been described earlier in this chapter. One difference that may be worth stressing again is the fact that the TRPV1 receptor is restricted to the peptidergic afferents in the mouse, but not in the rat (see above), raising concerns about the use of mouse transgenic models to study the function of this and other receptors.

While currently much emphasis is naturally placed on studying direct interactions between pairs of neurons to unravel the synaptic circuitry in the dorsal horn, a better understanding of the organization of the network will eventually require the integrative study of polysynaptic pathways (e.g., from primary afferents to spinal projection neurons). For example, cross talk between ascending pathways by means of polysynaptic connections regulated by local inhibitory circuits in the dorsal horn is likely a critical element underlying plasticity and pathology of the pain system (Yaksh, T. L., 1989; Sherman, S. E. and Loomis, C.W., 1994; Baba, H. *et al.*, 2003; Torsney, C. and MacDermott, A. B., 2006).

In summary, novel tools are emerging to allow us to improve our understanding of the structural and functional organization of the dorsal horn. These include novel markers, especially markers compatible with live cell studies such as transgenic animals expressing GFP in specific cell types (Hantman, A. W. *et al.*, 2004; Heinke, B. *et al.*, 2004; Dougherty, K. J. *et al.*, 2005; Zeilhofer, H. U. *et al.*, 2005) and the use of specific fluorescent ligands compatible with live cell studies (see e.g., Labrakakis, C. *et al.*, 2003; Labrakakis, C. and MacDermott, A. B., 2003). Novel methods are also emerging to identify neuronal pathways such as transsynaptic markers (Jasmin, L. *et al.*, 1997; Kissa, K. *et al.*, 2002; Braz, J. M. *et al.*, 2005). It also remains critical to combine these tools with other approaches to establish correlations between different identifiers of cell structure and function (e.g., morphology, transmitter/receptor phenotype, and electrophysiological properties). These steps are important to obtain a better grasp of the organization of the dorsal horn, which remains an essential condition for the understanding of nociceptive processing as well as of the neural basis of altered nociception in chronic pain conditions.

5.24.1 Organization of the Spinal Cord

The spinal cord consists of a wrapping of axons inside of which are neurons comprising the first relay for sensory information and motoneurons with axons that connect directly with skeletal muscles. In addition to sensory and motor integration, considerable sympathetic nervous system integration occurs in this structure. The neurons of the spinal cord are clustered together in a butterflylike arrangement, with the each of the two wings containing neurons representing or controlling muscles and skin in the right or left side of the body, respectively. The more posterior (or dorsal) portion of each wing is specialized for sensory function and is called the dorsal horn, while the more anterior (or ventral) portion is specialized for motor function and is called the ventral horn (see Figures 1 and 2).

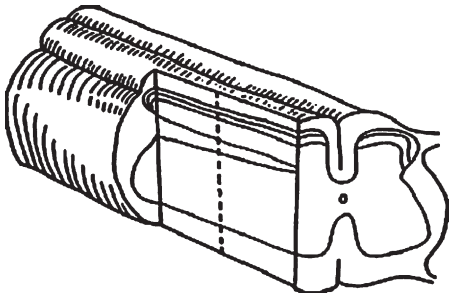

Figure 1 Cut-away view of lumbar spinal cord. From Light, A.R. 1992. Pain and Headache (Vol. 12): the Initial Processing of Pain and its Descending Control: Spinal and Trigeminal Systems. Karger, with permission.

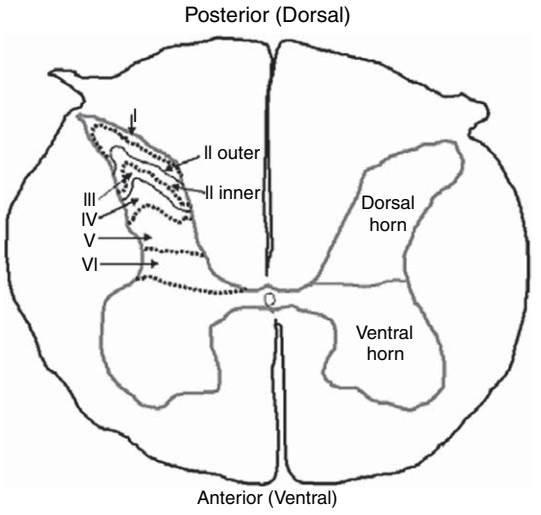

Figure 2 Laminae of the spinal cord dorsal horn.

5.24.2 Ventral Horn: Motor

The ventral horn contains all of the motoneurons whose axons leave the ventral horn in the ventral roots and directly innervate skeletal muscles of the body. However, most of the neurons in the ventral horn have axons that remain in the spinal cord and are, therefore, interneurons and are involved in motor integration. For the purposes of this chapter, the ventral horn is most important for the integration of reflexes. The most important of which are nociceptive reflexes. The most notable of the nociceptive reflexes is the flexion reflex which is often used as a surrogate for a response to pain, although the flexion reflex can often be regulated in different ways than the perception of pain (Mauderli, A. P. *et al.*, 2000). This chapter will not consider the ventral horn in detail. The axons surrounding the ventral gray matter are of interest in the physiology of pain systems, as the axons of many nociceptive (and non-nociceptive) neurons in the dorsal horn travel in the white matter of the ventral horn. Some ascend all the way to the thalamus, or even hypothalamus.

5.24.3 Dorsal Horn: Sensory

The dorsal horn consists of the terminations of primary afferent neurons whose cell bodies lie in the dorsal root ganglia, and many interneurons with terminations within the spinal cord. The dorsal horn also contains many transmission neurons with axons that leave the spinal cord and terminate in the brainstem (medulla and pons), thalamus, and hypothalamus (see Chapter Ascending Pathways: Anatomy and Physiology for more information on the ascending pathways originating from the spinal cord).

The dorsal horn also receives many inputs from higher brain centers that can modify, or in some cases, completely inhibit transmission from primary afferent neurons to other brain centers, including the ventral horn (see Chapter Descending Control Mechanisms for more information on descending modulatory pathways).

5.24.4 Laminar Organization

Many scientists have described the organization of the dorsal horn as laminar. Rexed B. (1952) divided the dorsal horn into six layers or laminae defined by the sizes and shapes of the cells within them (see Figure 2). Other defining characteristics of these laminae are the orientation of axons and dendrites of the neurons within them, and the amount of myelin that coats the axons in each layer (Clarke, J. L., 1859). The most dorsal, or superficial laminae (laminae I and II) as well as one of the deepest layers (lamina V) are most often associated with nociception (Light, A. R., 1992). While these laminae were originally defined using anatomical criteria (see chapter 9) they prove to also segregate some of the physiology of sensory systems of the spinal cord.

5.24.5 Laminae I and II (the Substantia Gelatinosa)

Because of its peculiar appearance in fresh tissue, the gelatinous translucent region that caps the dorsal horn has been called the substantia gelatinosa. This

region was defined as lamina II by Rexed B. (1952). Capping the substantia gelatinosa is the even more superficial lamina I, also called the substantia spongiosa or marginal zone (Waldeyer, W., 1889; Ramon Y Cajal, S., 1909). These regions have been associated with nociception since at least the time of Ranson (Ranson, S. W., 1913; 1914; 1915; Ranson, S. W. and von Hess, C. L., 1915; Ranson, S. W. and Billingsley, P. R., 1916; Ranson, S. W. and Davenport, H. K., 1931). Ranson made the association between the translucent appearance of these regions and the lack of myelinated axon terminations in these regions and the likely termination of unmyelinated axons, which even then he associated with pain.

Fifty years later, lamina I and II were definitively shown to contain neurons that specifically responded to noxious (noxious meaning tissue damaging) stimuli and others responding to innocuous thermal stimuli (Christensen, B. N. and Perl, E. R., 1969; 1970; Mosso, J. A. and Kruger, L., 1973). Some of these neurons were shown to project through the anterolateral tract to the thalamus (Kumazawa, T. *et al.*, 1971; 1975; Craig, A. D. and Kniffki, K. D., 1985). However, these investigators also showed that laminae I and II integrated more than purely nociceptive inputs with innocuous thermal neurons found in lamina I and innocuous mechanical neurons found in lamina II.

5.24.6 The Adequate Stimulus

Physiological descriptions of nociceptive neurons in the spinal cord dorsal horn are often based on the adequate stimulus (see chapter 2 for a thorough discussion of the adequate stimulus). We define this as the best (most effective) natural (most likely to occur in an environment not manipulated by humans) stimulus that excites (evokes action potentials) in a neuron. For example, while punctate pressure that does not cause immediate harm to the skin may occasionally evoke an action potential in a spinal neuron, if that neuron fires a train of action potentials at 100 Hz to punctuate pressure that damages the skin, then the adequate stimulus is presumed to be noxious mechanical stimulation. If this same neuron responds to electrical shock, its adequate stimulus is not presumed to be electrical stimulation. Electrical shock is unlikely to occur in a world without human intervention.

5.24.7 Physiology of Neurons in the Dorsal Horn by Laminae

Being largely sensory in nature, the types of peripheral stimuli that activate the intrinsic neurons of the dorsal horn are strongly related to the physiological types of primary afferents that synapse on the spinal neurons. A discussion of the properties of nociceptive primary afferents and their responses to peripheral stimuli of various types is found in chapter 4. Integration of these primary afferent inputs occurs to various degrees in the spinal neurons. Some neurons retain the modality selectivity of the primary afferents, while others integrate the input of more than one type of primary afferent.

5.24.8 Lamina I

5.24.8.1 Modality of Input to Lamina I

Most investigators agree that a substantial portion of lamina I (see Figure 2 for location in spinal cord) neurons respond specifically or preferentially to various forms of noxious stimuli (Light, A. R., 1992). In studies using cats, Light A. R. found that 63% of neurons identified as lamina I neurons by intracellular labeling were nociceptive while 12% responded to innocuous cooling (4%) or warming (cooling and warming neurons are referred to collectively as thermoreceptive neurons); 14% responded to innocuous mechanical stimuli, and 5% responded to both innocuous mechanical stimuli and noxious stimuli. Of the neurons with nociceptive inputs, 28% responded only to noxious mechanical stimuli while 35% responded to noxious mechanical stimuli, and also to noxious heat and chemical stimuli. Only some of these neurons were tested with noxious cold. Figure 3 shows some characteristic responses of lamina I cells.

Andrew D. and Craig A. D. (2002) determined that the types of inputs observed for lamina I neurons projecting to the thalamus were similar to those described for unidentified lamina I neurons. Some differences for identified spinothalamic neurons were a disproportionate percentage of neurons with thermal inputs in the spinothalamic population. Of 125 lamina I spinothalamic neurons, 61% were nociceptive and 39% were thermoreceptive (most responded to cooling, 35%, with the rest responding to innocuous warming, 4%). Andrew D. and Craig A. D. also found that the nociceptive neurons were classifiable into

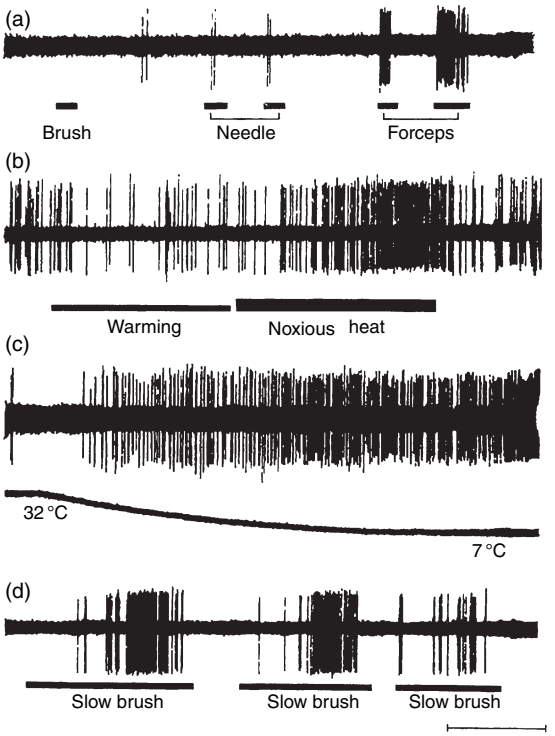

Figure 3 Responses of lamina I neurons (a) Neuron activated only by noxious mechanical stimulation of skin. (b) Neuron activated by both noxious mechanical stimuli (not shown) and noxious heating of the skin. (c) Neuron activated only by innocuous cooling of the skin. (d) Neurons activated only by innocuous mechanical stimulation of the skin. This neuron responded only to brushing at less than 10 cm s^{-1}. Scale bar = 10 s for (a), (b), and (d); 20 s for (c). From Light, A. R. 1992. Pain and Headache (Vol. 12): the Initial Processing of Pain and its Descending Control: Spinal and Trigeminal Systems. Karger. Reprinted with permission from Light, A. R., Trevino, D. L., and Perl, E. R. 1979. Morphological features of functionally defined neurons in the marginal zone and substantia gelatinosa of the spinal dorsal horn. J. Comp. Neurol. 186, 151–171. Copyright 1979, Wiley-Liss of John Wiley & Sons, Inc.

somewhat different groups than those summarized by Light A. R. (1992). Of the 61% nociceptive neurons, a minority (43%) were described as nociceptive specific. Of the nociceptive-specific neurons, most (80%) were responsive to both noxious mechanical and noxious heat stimuli, with only 20% responsive to only mechanical stimuli. The majority (57%) of the nociceptive neurons was classified as responding to heat, pressure, and cold (HPC). These neurons responded not only to noxious mechanical pressure, but also responded to innocuous cooling temperatures. Craig (Andrew, D. and Craig, A. D., 2002) has also determined the quantitative response properties of lamina I nociceptive neurons (see Figure 4). The data presented in these publications clearly indicate that lamina I neurons are capable of reliably detecting and transmitting precise quantitative information about noxious pressure to higher centers (Craig, A. D. and Andrew, D., 2002). These authors showed the quantitative responses of lamina I neurons to activation by noxious heat. The responses correlate very well with human pain ratings of the same stimuli (see Figure 5).

In addition to nociceptive and thermal inputs, lamina I neurons also encode stimuli interpreted as itch and metabolic signals produced by contracting muscles.

Craig's laboratory reported recording neurons in lamina I that specifically respond to stimuli provoking itch (Andrew, D. and Craig, A. D., 2001; see Figure 6), and others that responded only to actively contracting muscles (Wilson, L. B. *et al.*, 2002; see Figure 7). Some of the neurons responding only to actively contracting muscles may represent metaboreceptors that encode the metabolites produced by actively contracting muscles, and may be the peripheral receptors that are capable of encoding the signals interpreted as muscle fatigue, and/or muscle pain. These neurons may also be the sensory arm of sympathetic reflexes known to be activated by actively contracting muscles (Rotto, D. M. and Kaufman, M. P., 1988).

While the detailed neuronal properties presented here were obtained from recordings in cats, similar percentages of these various types of neurons in lamina I have been found in monkeys (Kumazawa, T. *et al.*, 1975; Kumazawa, T. and Perl, E. R., 1978; Light, A. R. *et al.*, 1979; Price, D. D. *et al.*, 1979; Chung, J. M. *et al.*, 1986; Craig, A. D., 2004) and rats (Giesler, G. J., Jr. *et al.*, 1976; Menetrey, D. *et al.*, 1977; Light, A. R. and Willcockson, H. H., 1999) although some of those referenced here report many more neurons responding to both noxious and non-noxious stimuli in the wide-dynamic-range (WDR) fashion (see chapter 10.1 for more information). Very recently, similar types of neurons have also been reported in lamina I of the mouse, in an *ex vivo* preparation in mouse (Koerber, H. R., personal communication, 2007).

5.24.8.2 Receptive Field Characteristics

The receptive fields of lamina I neurons range from quite small (1 mm^2) to quite large (1000 mm^2) depending on the body part encoded. The smallest receptive fields are found on the digits, while the

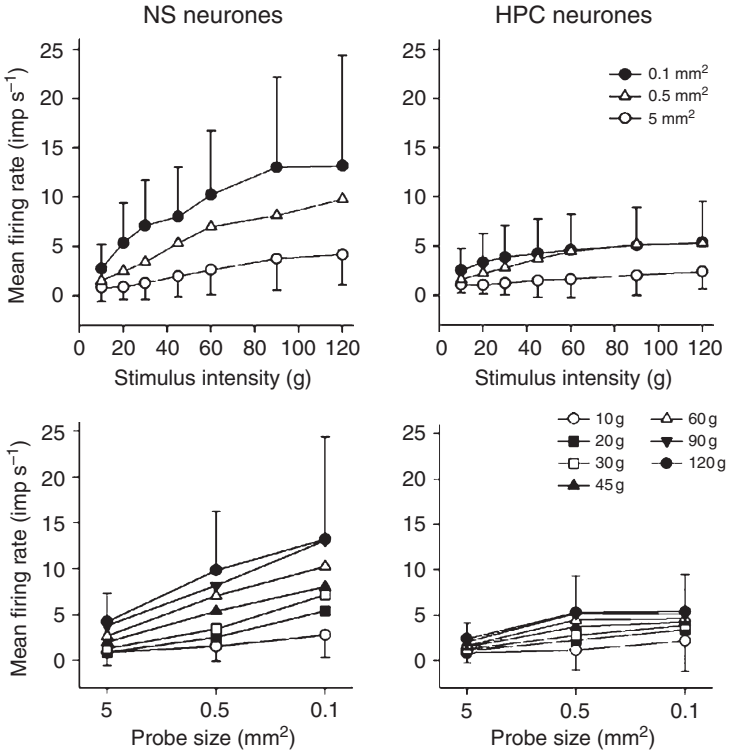

Figure 4 Quantitative responses of lamina I neurons Mean population stimulus–response curves to graded mechanical stimulation (10–120 g) for NS ($n = 20$) and HPC ($n = 19$) neurones (top row). The same data replotted with respect to toprobe size are shown in the bottom row. NS, nociceptive-specific neurons; HPC, heat, pressure, and cold. From Andrew, D. and Craig, A. D. 2002. Quantitative responses of spinothalamic lamina I neurones to graded mechanical stimulation in the cat. J. Physiol. 545, 913–931, reprinted with permission.

largest are found on the back and hip. The receptive field sizes and pattern indicates considerable convergence from primary afferent neurons. Thus, the smallest excitatory receptive fields for lamina I neurons can approximate the size of C-primary afferent polymodal nociceptors (<1 mm). The largest excitatory receptive fields, however, are many times the size of the largest primary afferent receptive field. Lamina I neurons with A-fiber nociceptive input do not have the spotlike receptive fields of the primary afferents, but have a more uniform receptive field, indicating convergence of several A-nociceptors onto the lamina I neurons.

Excitatory receptive fields often have an inhibitory surround region, stimulation of which with noxious stimuli causes inhibitory post synaptic potentials (IPSPs)in the recorded neuron and can inhibit activation induced by stimulation of the more central excitatory receptive field (see Figure 8 for explanation of how these receptive fields are formed).

5.24.9 Projections and Function of Lamina I Neurons

While many of the neurons in lamina I most likely function as integrative interneurons within lamina I, a large proportion of these neurons project to other spinal cord and brain regions.

Many of the neurons in lamina I have been shown to project to higher brain centers including the thalamus, the parabrachial region, the medullary reticular formation, and even the hypothalamus (see chapter 14 for more on this topic). A much larger proportion of lamina I cells have been shown to project to higher brain centers than neurons located in laminae II-IV. Craig A. D. (1996; 2003) has also found lamina I projection neurons responding specifically to itch inputs, and others responding specifically to ergoreception (inputs from actively contracting muscles; see above). He has attempted to generalize these inputs as homeostasis inputs, that is, inputs necessary to maintain body integrity.

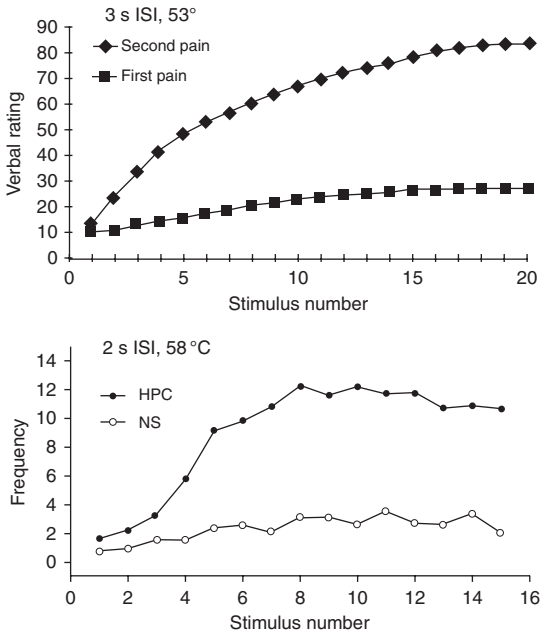

Figure 5 Comparison of the mean response curves of heat, pressure, and cold (HPC) and nociceptive-specific (NS) lamina I spinothalamic tract cells (bottom) to the maximal repeated brief contact heat stimulus trial with the mean report of human subjects to the maximal trial in the study of Vierck *et al*. (1997) (top). In the top panel, 53 DEG = 53°C; ISI = Interstimulus interval. From Craig, A. D. and Andrew, D. 2002. Responses of spinothalamic lamina I neurons to repeated brief contact heat stimulation in the cat. J. Neurophysiol. 87, 1902–1914, reprinted with permission.

Thus, one of the major functions of lamina I is to convey information about nociceptive inputs, itch, and thermal inputs, to higher brain centers . Lamina I also integrates and relays inputs necessary for sympathetic functions. Craig has grouped these functions as homeostatic and suggests the view that lamina I is critical for relatively objective information about body integrity necessary to maintain homeostasis, and thus, life (Craig, A. D., 1996; 2003).

5.24.10 Lamina II

Almost 30 years after the first definitive recordings were made from the substantia gelatinosa, the function of this region is still not understood. Recordings combined with intracellular labeling suggested that the anatomically observable division of lamina II into an inner and outer region had an apparent functional correlation.

5.24.11 Outer Lamina II

5.24.11.1 Modality of Input to Outer Lamina II

The outer region contains mostly nociceptive neurons while the inner region contains mostly innocuous mechanically responsive neurons (see Figure 9 for recordings of common responses). This relationship has been shown in cats, monkeys, and rats (Kumazawa, T. and Perl, E. R., 1978; Bennett, G. J. *et al*., 1979; Light, A. R. *et al*., 1979; Bennett, G. J. *et al*., 1980; Light, A. R. *et al*., 1981; Light, A. R. and Kavookjian, A. M., 1984; Steedman, W. M. *et al*., 1985; Light, A. R. and Willcockson, H. H., 1999).

In a summary of data from experiments in the Light and Perl laboratory (Light, A. R., 1992), 70% of the neurons identified as having cell bodies in lamina IIo were nociceptive. Forty-eight per cent responded only to mechanical nociceptive inputs, while 32% responded to at least noxious heat and noxious mechanical inputs, and many that were tested, also responded to noxious chemicals, making them polymodal nociceptive inputs. Of the remainder, 20% responded to both innocuous and noxious mechanical inputs and 5% each were thermoreceptive (most to cooling) and 5% responded only to innocuous mechanoreceptive stimuli.

The neurons in the outer region of lamina II have small receptive fields, and neurons can receive only noxious mechanical inputs, only noxious heat or cold inputs, and mixtures of mechanical and heat, and noxious chemical inputs. Summarizing data from several publications (Light, A. R. *et al*., 1979; Light, A. R. and Kavookjian, A. M., 1984; Light, A. R. and Kavookjian, A. M., 1988; Light, A. R. and Willcockson, H. H., 1999), some 70% of lamina IIo neurons are nociceptive, 5% are thermoreceptive, 5% are responsive to innocuous mechanical stimuli, and 20% respond to both innocuous mechanical stimuli and nociceptive stimuli. Similar to lamina I neurons, some of the nociceptive neurons respond selectively to noxious mechanical inputs, with perhaps more of these than other types. Other nociceptive neurons respond to noxious heat as well as to noxious mechanical stimuli.

5.24.11.2 Receptive Field Characteristics

The receptive fields of lamina IIo neurons tend to be smaller than those of the overlying lamina I

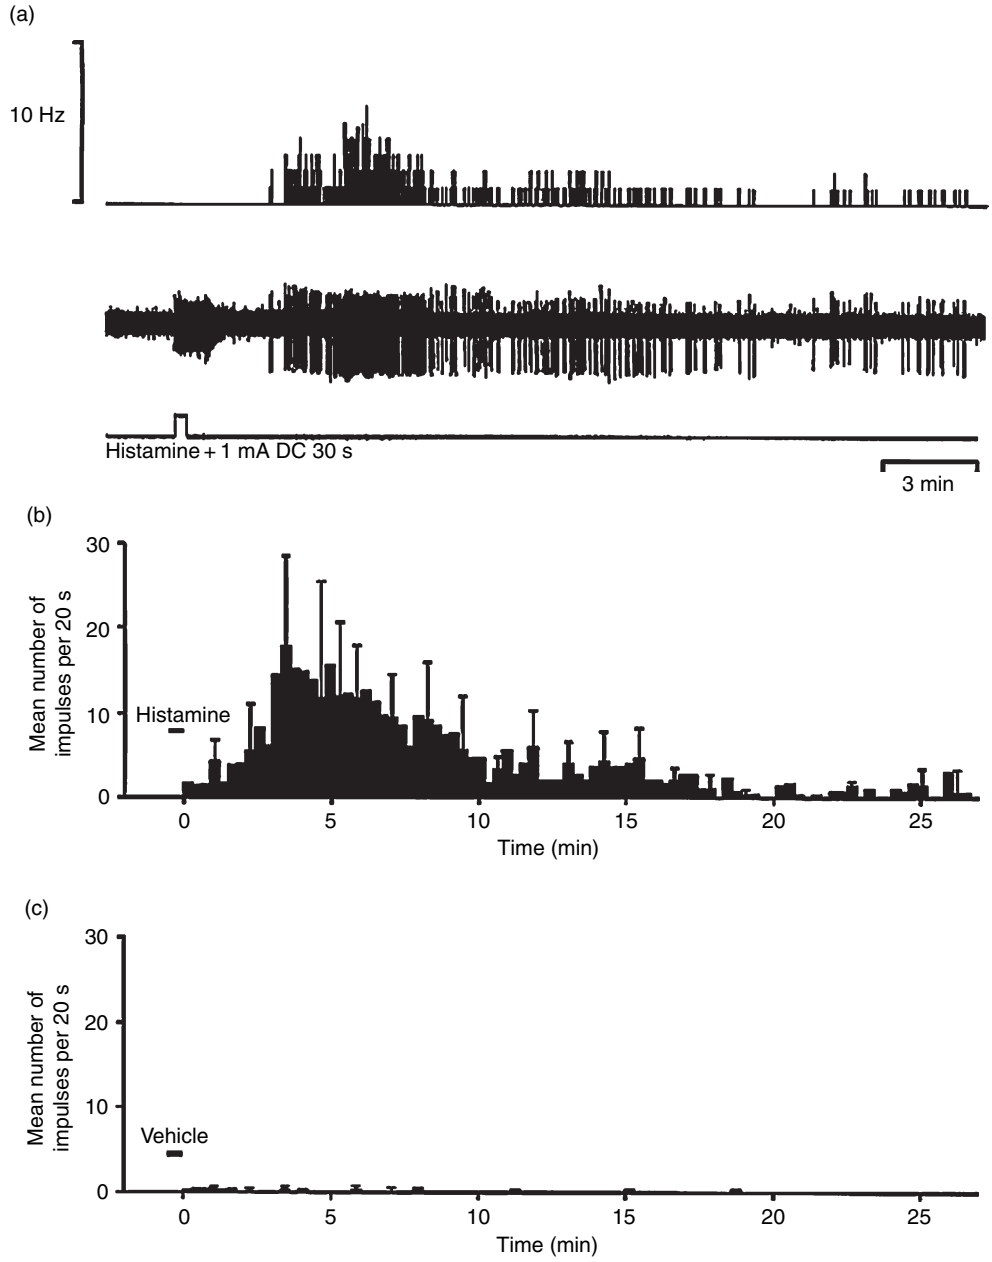

Figure 6 Histamine- and vehicle-evoked responses from histamine-sensitive lamina I spinothalamic tract neurons. (a) The response of a single neuron to histamine. Top histogram, binned firing rate of the neuron (1-s bins). The middle trace shows the analog record of neuronal activity; the thickening of the baseline in this record during the iontophoresis (indicated by the lower trace) is due to the current-evoked activation of several neighboring neurons. (b) Mean response of all 10 histamine-sensitive lamina I spinothalamic tract neurons to histamine application. (c) Mean responses of the same 10 neurons to vehicle application. Error bars, 1 standard deviation; bin size, 20 s; DC, direct current. With permission from Andrew, D. and Craig, A. D. 2001. Spinothalamic lamina I neurons selectively sensitive to histamine: a central neural pathway for itch. Nat. Neurosci. 4, 72–77.

neurons (Price, D. D. *et al.*, 1979). This may be due to the less extensive mediolateral spread of dendrites of lamina II neurons (see chapter 9). Lamina II neurons may also have fewer complex receptive fields, sometimes lacking an inhibitory surround region. These two observations, along with some

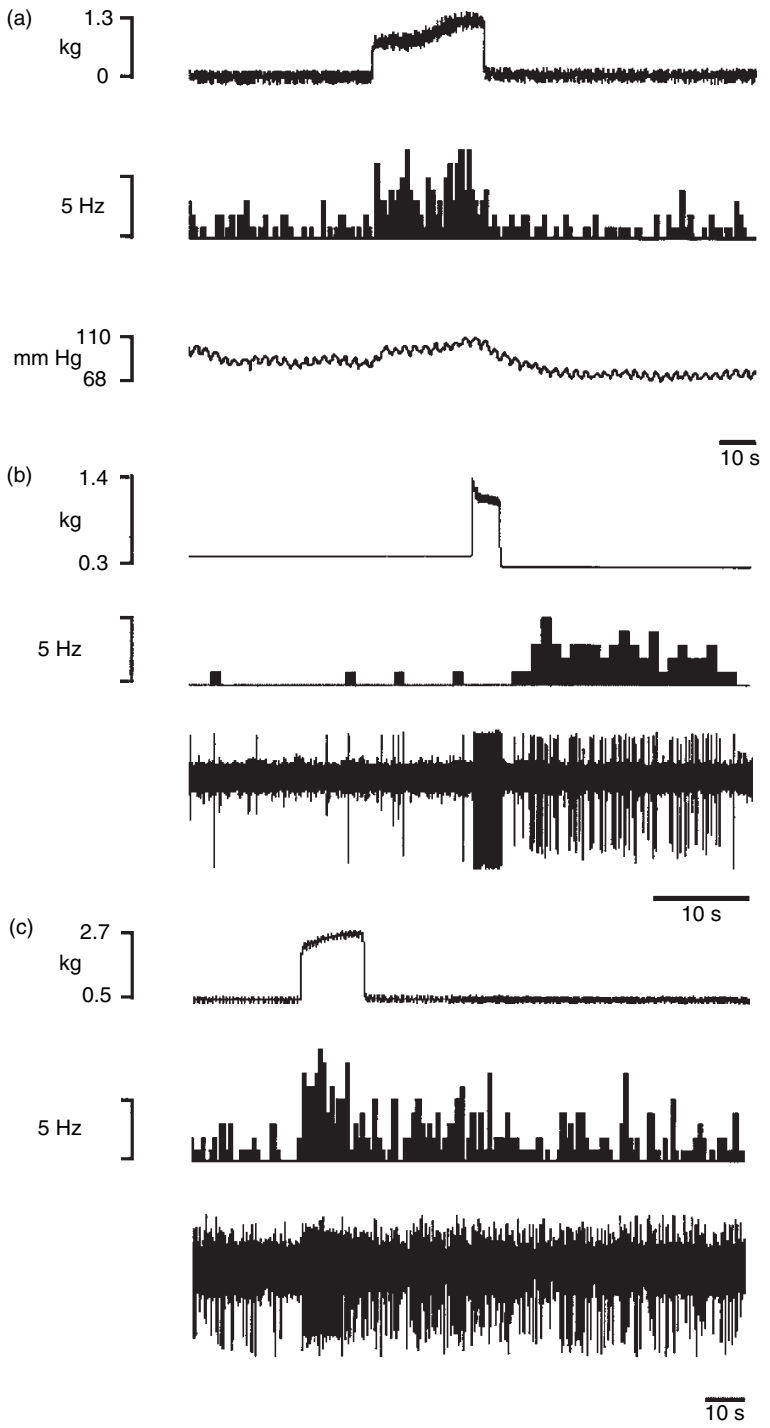

Figure 7 Examples of the variety of responses of lamina I neurons that were excited by muscle contraction. The traces show from the top downward: the tension developed in the triceps surae muscle, the discharge of the single neuron histogrammed in 1 s bins and either mean blood pressure (a) or the neural recording ((b) and (c)). (a) Response from a heat, pressure, and cold (HPC) lamina I neuron with unidentified projections that was excited by contraction that paralleled the tension developed in the muscle and the centrally evoked cardiovascular reflex. (b) Response of another HPC lamina I neuron with unidentified projections that was only excited after the contraction. (c) Response of a spinobulbar lamina I neuron (central conduction velocity 2.2 m s^{-1}) that was excited during and after the contraction; this neuron had no identifiable cutaneous receptive field but responded to stretching the triceps muscle and also to rhythmic contractions at 5 Hz. From Wilson, L. B., Andrew, D., and Craig, A. D. 2002. Activation of spinobulbar lamina I neurons by static muscle contraction. J. Neurophysiol. 87, 1641–1645, reprinted with permission.

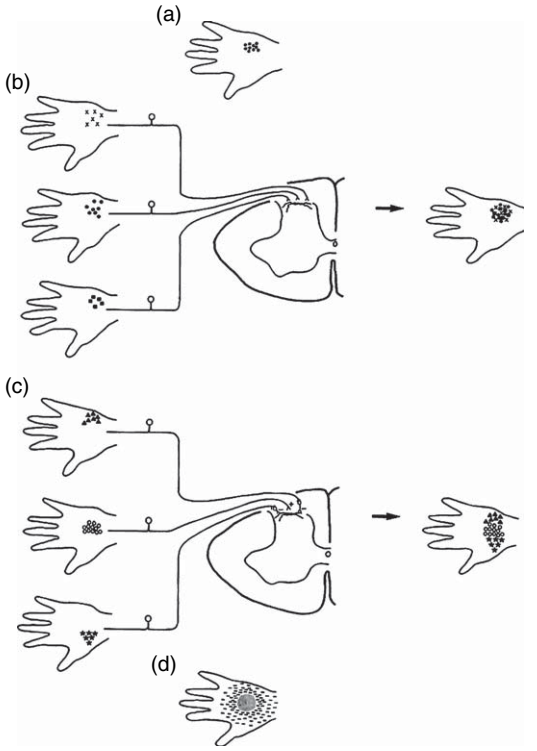

Figure 8 Diagram of mechanisms of integration of nociceptive inputs in lamina I neurons. (a) Indicates the receptive field of a single primary afferent nociceptor with an Aδ axon. Each spot represents a point at which noxious mechanical stimulation evokes a discharge. (b) Left panel indicates the receptive fields of three mechanical nociceptors with overlapping receptive fields. The three primary afferents terminate on the same lamina I neuron in the middle panel. The right panel indicates the resulting receptive field. The receptive field is somewhat larger, and more responsive points are found within the responsive area. Thus, unlike primary afferent receptors, spinal nociceptive neurons have nearly continuous receptive fields with less unresponsive regions between responsive spots. (c) Left panel indicates the receptive fields of three nonoverlapping primary afferent mechanical nociceptors. The middle panel indicates that the lamina I neuron receives excitatory input from the axons whose receptive field is indicated with open circles. The other two axons excite inhibitory neurons (this is a simplification), and in all cases, both excitatory and inhibitory neurons are excited by all primary afferent neurons). The result is that the receptive field of the lamina I neuron, shown at right, consists of inhibitory inputs (shown with filled symbols) and excitatory inputs (shown with open symbols). (d) This receptive field is typical for spinal cord nociceptive neurons and indicates both of the processes described in (a)–(c). The central crosshatched region is the excitatory receptive field in which noxious mechanical stimulation causes excitation of the spinal neuron. Noxious mechanical stimulation of the region outside the excitatory receptive field causes inhibition and is indicated by minus signs. This inhibitory field fades out gradually as the distance from the excitatory field increases. Adapted from Light, A. R. 1992. Pain and Headache (Vol. 12): the Initial Processing of Pain and its Descending Control: Spinal and Trigeminal Systems. Karger, reprinted with permission.

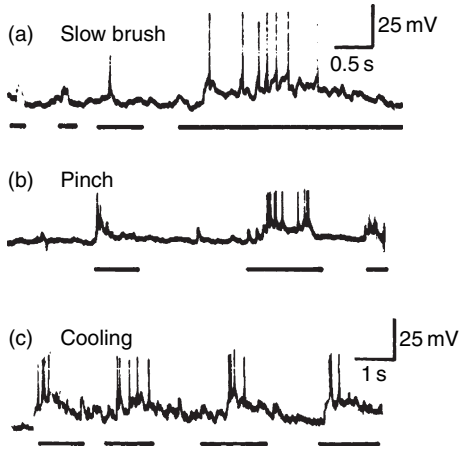

Figure 9 Low-gain, direct-current patch-clamp recordings *in vivo* from the most common types of responsive neurons encountered in the substantia gelatinosa of rats. Examples of slow brush (a), pinch (b), and innocuous cooling (c) (ethyl chloride spray applied to brush and brushed on skin) responsive neurons. From Light, A. R. and Willcockson, H. H. 1999. Spinal laminae I–II neurons in rat recorded in vivo in whole cell, tight seal configuration: properties and opioid responses. J. Neurophysiol. 82, 3316–3326, reprinted with permission.

anatomical findings (see chapter 9) suggest that at least some lamina II neurons project inputs to overlying lamina I neurons.

5.24.12 Projections and Function of Outer Lamina II Neurons

In addition to projections to lamina I, lamina IIo neurons have been shown to project to deeper laminae, including laminae III, IV, and V (Light, A. R. and Kavookjian, A. M., 1988; Eckert, W. A., III, *et al.*, 2003). Substantial intralaminar projects have also been noted for many years (Szentagothai, J., 1964; Matsushita, M., 1969; Rethelyi, M. and Szentagothai, J., 1969; Rethelyi, M. *et al.*, 1981; 1983; 1989). Both inhibitory and excitatory intralaminar, as well as extralaminar connections, are possible (Lu, Y. and Perl, E. R., 2005). A few neurons in lamina II have also been shown to project long connections to the thalamus (Giesler, G. J., Jr. *et al.*, 1978; Willis, W. D. *et al.*, 1978). Whether these projections represent ectopic lamina I neurons, or more projections of this variety have yet to be detected is unknown.

Thus, lamina IIo neurons may function both as inhibitory neurons helping to create the inhibition surround receptive fields described above, and as

excitatory relay neurons for convergence of receptive fields and possible amplification of the excitatory signal (see Figure 8).

5.24.12.1 Inner Lamina II (II_i)

The inner division of lamina II has many neurons that respond to innocuous mechanical stimuli (Light, A. R. *et al.*, 1979; Price, D. D. *et al.*, 1979; Woolf, C. J. and Fitzgerald, M., 1983; Light, A. R. and Kavookjian, A. M., 1988; Light, A. R. and Willcockson, H. H., 1999). A detailed analysis of the types of inputs to this lamina has not been made. One survey (Light, A. R., 1992) found that between 50% and 80% of the neurons responded only to innocuous mechanical stimuli. A very common response was a preferential response to a very slowly moving stimulus (e.g., see Figure 9(a)). The response to mechanical stimulation often adapts with very few repetitions of the stimulus, sometimes after only a single stimulation. Responses of this type do not relate directly to any known type of primary afferent input. Intracellular analysis of these response properties identified a prominent IPSP evoked by innocuous mechanical stimulation that was capable of inhibiting nearly all action potential generation (Light, A. R. *et al.*, 1979). Neurons with these types of inputs seem to dominate this sublamina.

However, in addition to innocuous mechanical inputs, considerable circumstantial evidence suggests that nociceptive inputs should also reach inner lamina II. First, a few neurons in this layer have been found to be activated preferentially by nociceptive stimuli. Second, primary afferents labeling with isolectin B4 (IB4) terminate heavily in inner lamina II. At least some of the IB4-positive afferents have been identified as nociceptive, and eliminating IB4-containing primary afferents reduced inflammatory pain in rats. vanilloid receptor like 1 (VRL-1 also called TRPV2)also labels inner lamina II suggesting that a population of myelinated nociceptor may selectively terminate in this region (Lewinter, R. D. *et al.*, 2004). Neurons in lamina IIi show increases in protein kinase Cγ (PKCγ) following inflammation which results in allodynia (Martin, W. J. *et al.*, 1999; 2001). At least a few nociceptive primary afferent fibers have shown extensive terminations in lamina IIi (Sugiura, Y. *et al.*, 1986; Koerber H. R. *et al.*, personal communication, 2004). Finally, either muscle nociceptive input to laminae IIi cells, and/or muscle metaboreceptor input to this layer is predicted by the terminations of single group IV muscle afferents in this layer (Ling, L. J. *et al.*, 2003).

Potentially then, nociceptive neurons, and possibly, metaboreceptive neurons should be found in inner lamina II. Whether these neurons represent special types of nociceptive inputs (such as inputs sensitive to inflammation) or have nociceptive inputs (such as muscle nociceptive inputs) that have not been found in recording studies thus far remains to be examined.

5.24.12.1.1 Projections and function of inner lamina II neurons

Like other neurons in lamina II, lamina IIi has substantial axonal projections to other regions of lamina II (Szentagothai, J., 1964; Matsushita, M., 1969; Rethelyi, M. and Szentagothai, J., 1969; Rethelyi, M. *et al.*, 1981; 1983; 1989). In addition, at least some of these neurons project axons to deeper laminae, where they synapse with other spinal cord neurons (Light, A. R. and Kavookjian, A. M., 1988; Eckert, W. A., III, *et al.*, 2003). Basbaum's laboratory has also recently proposed that neurons in this region project to lamina V neurons which subsequently project to higher brain regions, not usually considered in nociceptive processing (Braz, J. M. *et al.*, 2005).

The innocuous responses of lamina IIi neurons seems most related to sensuous touch (Olausson, H. *et al.*, 2002) or tickle. As these neurons have not been shown to project in large numbers to the thalamus or other brain regions rostral to the spinal cord, it is unknown how these inputs are relayed to higher brain centers. However, it is interesting that some have noted that tickle is abolished following lesions of the anterolateral tract (Lahuerta, J. *et al.*, 1990).

5.24.12.2 Lamina III

Lamina III mostly contains neurons that receive only innocuous mechanical inputs (Pomeranz, B. *et al.*, 1968; Price, D. D. and Mayer, D. J., 1974; Wall, P. D. *et al.*, 1979; Light, A. R. and Durkovic, R. G., 1984). However, at least some nociceptive neurons can be found here. Nociceptive neurons in lamina III may respond only to noxious mechanical stimuli, or to noxious thermal and chemical stimuli as well as to noxious mechanical stimuli (Brown, A. G. and Fyffe, R. E., 1981; Maxwell, D. J. *et al.*, 1983; Maxwell, D. J. and Koerber, H. R., 1987). Most investigators have reported that neurons that do respond to noxious stimuli, also respond to innocuous stimuli, albeit with much lower action potential frequency. The importance of lamina III in nociception is unknown. In cats, many lamina III

neurons project to the lateral cervical nucleus. In rats and primates, at least some of these neurons project to the dorsal column nuclei (Rustioni, A. *et al.*, 1979; Giesler, G. J., Jr. *et al.*, 1984). As with lamina IIi, PKCγ is upregulated in lamina III neurons following nerve injury and inflammation (Polgar, E. *et al.*, 1999; Miletic, V. *et al.*, 2000), suggesting at least inflammatory inputs, if not nociceptive inputs to this lamina.

5.24.12.3 Lamina IV

Lamina IV neurons are also dominated by responses to innocuous mechanical stimuli (Armett, C. J. *et al.*, 1962; Pomeranz, B. *et al.*, 1968; Price, D. D. and Browe, A. C., 1973). Many other neurons, however, respond more vigorously to noxious stimuli (both mechanical and thermal) than to innocuous stimuli (the WDR response). In cats, for example, Light A. R. and Durkovic R. G. (1984) found that 56% of the recorded neurons responded only to innocuous mechanical stimuli, while 37% responded to innocuous stimuli, but increased their response rate to noxious stimuli. Only 6% of the neurons responded only to noxious stimuli. In cats, a substantial number of lamina IV neurons project to the lateral cervical nucleus and are, therefore, spinocervical neurons (Brown, A. G., 1968; Brown, A. G. and Franz, D. N., 1969; Bryan, R. N. *et al.*, 1973; 1974). At least some of these neurons encode some aspects of noxious stimuli. The proportion of spinocervical neurons in primates appears to be less than in cats (Bryan, R. N. *et al.*, 1974). Again some of these neurons encode noxious stimuli (Brown, A. G., 1968; Brown, A. G. and Franz, D. N., 1969; Bryan, R. N. *et al.*, 1973; 1974; Kajander, K. C. and Giesler, G. J., Jr., 1987). Specific functions for noxious inputs relayed via the spinocervical tract are unknown, but may represent an alternative pathway for pain transmission, separate from the spinothalamic tract (Willis, W. D. and Westlund, K. N., 1997). Finally, at least some lamina IV neurons project to the thalamus (Trevino, D. L. *et al.*, 1973; Albe-Fessard, D. *et al.*, 1974; Trevino, D. L. *et al.*, 1974; Willis, W. D. *et al.*, 1974; Price, D. D. and Mayer, D. J., 1975).

5.24.12.4 Lamina V

A very large literature exists on the nociceptive properties of neurons in lamina V (Wall, P. D., 1967; Mendell, L. M. and Wall, P. D., 1965; Hillman, P. and Wall, P. D., 1969; Wall, P. D., 1973; Price, D. D. and Dubner, R., 1977; Dubner, R., 1978; Dubner, R. and Bennett, G. J., 1983; Willis, W. D., 1985; 1988). This is partly due to the relative ease of recording the larger neurons located in this layer, and partly due to its known large projection to the thalamus, making it a large contributor to the spinothalamic tract and this tract has long been implicated as a pain transmission pathway.

Lamina V contains many neurons that respond to both noxious and innocuous stimuli, and also neurons that respond selectively to noxious stimuli. Innocuous mechanoreceptive neurons are also found in this lamina (Mendell, L. M. and Wall, P. D., 1965; Hillman, P. and Wall, P. D., 1969; Light, A. R. and Durkovic, R. G., 1984).

The receptive fields of lamina V neurons tend to be larger than neurons with similar modalities in lamina I–IV. A common feature of the receptive fields, like those in lamina I, is a zone of inhibitory influence surrounding the excitatory receptive field (inhibition surround). Typically, the most effective stimulus for eliciting inhibition is the same as that of the excitatory region (Hillman, P. and Wall, P. D., 1969).

The response characteristics of at least some lamina V neurons correlate well with human estimates of pain intensity and with reflex response of animals to noxious stimuli (Dubner, R. *et al.*, 1977; 1980; Casey, K. L., 1982; Dubner, R. *et al.*, 1989; e.g., see figure 10). This, along with the fact that many lamina V neurons project in the anterolateral tract to the thalamus, both of which are implicated in pain transmission, indicate that lamina V neurons are important in at least some aspects of pain perception. The likely contribution of lamina V neurons to the flexion reflex pathway probably contributes to the observations that lamina V neuron responses are similar to nociceptive reflexes (Light, A. R. and Durkovic, R. G., 1984; Morgan, M. M., 1998).

The presence of innocuous activation of many lamina V neurons in addition to nociceptive activation requires additional mechanisms to allow discrimination between innocuous and noxious stimuli.

5.24.13 The Ventral Horn
